

Programming Assignment 2: Routing Protocol

Assigned: October 16, 2007

Due: November 1, 2007, 11:59pm

1 Problem Statement

In this assignment you will implement a simplified version of *Distance Vector Protocol* in P&D 4.2. The protocol will be run on top of servers (behaving as routers) using UDP. Each server runs on a machine at a pre-defined port number. The servers should be able to output their forwarding tables along with the cost and should be robust to link changes. (Note: we would like you to implement the basic algorithm, count to infinity, **not** poison reverse)

2 Protocol Specification

The various components of the protocol are explained step by step. Please strictly adhere to the specifications.

2.1 Topology Establishment

Each server is supplied with a topology file at startup that it uses to build its initial routing table. The topology file is local and contains the link cost to the neighbours. For all other servers in the network, the initial cost would be infinity. The topology file looks as follows:

- <num-servers>
- <num-neighbors>
- <server-ID> <server-IP> <server-port>
- <server-ID1> <server-ID2> <cost>

num-servers: total number of servers

server-ID,server-ID1,server-ID2: An unique identifier for a server (in this project, they are an integer)

cost: cost of a given link between a pair of servers. Assume that cost is an integer value.

Consider the topology in fig 1.

Figure 1: Example topology

Line number	Line entry	Comments
1	5	number of servers
2	3	number of edges or neighbours
3	2 128.8.6.1 4094	server-id 2 and corresponding IP, port pair
4	3 128.8.6.2 4096	server-id 3 and corresponding IP, port pair
5	4 128.8.6.3 7091	server-id 4 and corresponding IP, port pair
6	5 128.8.3.1 7864	server-id 5 and corresponding IP, port pair
7	1 2 7	server-id and neighbor id and cost
8	1 3 4	server-id and neighbor id and cost
9	1 4 5	server-id and neighbor and cost

IMPORTANT: Please adhere to this format for the topology file. In this environment, costs are bi-directional i.e. the cost of a link from A-B is the same for B-A. Whenever a new sever is added to the network, it will read its topology file to determine who its neighbors are. Routing updates are exchanged periodically between neighboring servers. When this newly added server sends routing messages to its neighbors, they will add an entry in their routing tables corresponding to it. Servers can also be removed from a network. When a server has been removed from a network, it will no longer send distance vector updates to its neighbors. When a server no longer receives distance vector updates from its neighbor for three consecutive update intervals, it assumes that the neighbor no longer exists in the network and makes the appropriate changes to its routing table (link cost to this neighbor will now be set to infinity). This information is propagated to other servers in the network with the exchange of routing updates. Please note that although a server might be specified as a neighbor with a valid link cost in the topology file, the absence of three consecutive routing updates from this server will imply that it is no longer present in the network.

Note: There are two situations that servers will send out the update packet to its immediate neighbors.

- The server's periodic update
- Users use "step" command to ask the server to do it

2.2 Routing Updates

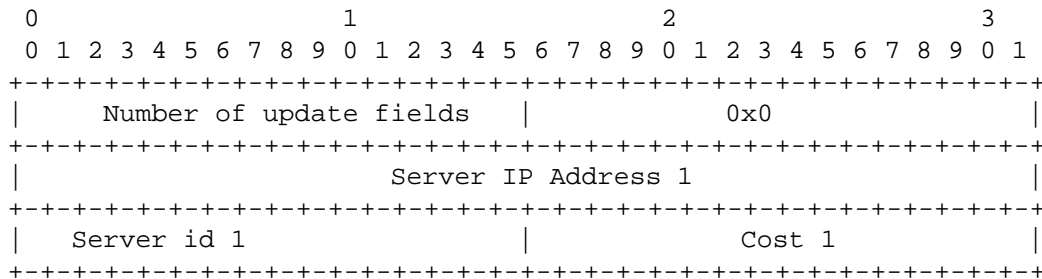

Routing updates are exchanged periodically between neighboring servers based on a time interval specified at the startup. In addition to exchanging distance vector updates, servers must also be able to respond to user- specified events. There are 4 possible events in this system. They can be grouped into three classes: topology changes, queries and exchange commands. Topology changes refer to an updating of link status (update). Queries include the ability to ask a server for its current routing table (display), and to ask a server for the number of distance vectors it has received (packets). In the case of the packets command, the value is reset to zero by a server after it satisfies the query. Exchange commands can cause a server to send distance vectors to its neighbors immediately (triggered update). Examples of these commands include:

- update 1 2 inf
The link between the servers with IDs 1 and 2 is assigned to infinity.
- update 1 2 8
Change the cost of the link to 8.
- step
Send routing update to neighbors (triggered/force update) right away. Note that routing updates **otherwise** just happen periodically.
- packets
Display the number of distance vector packets this server has received since the last instance when this information was requested.
- disable server-id
Disable the link to given server. Here you need to check if the given server is its neighbor.

- **crash**
Emulates a server crash. Close all connections on all links. The neighbouring servers must handle this close correctly and set the link cost to infinity.
- **display**
Display the current routing table. The display should be formatted as a sequence of lines, with each line indicating: <destination-server-ID> <next-hop-server-ID> <cost-of-path>

2.3 Message Format

Routing updates are sent using the General Message format. All routing updates are unreliable messages. The message format for the data part is:

- **Number of Update Fields:** (2 bytes) Indicate the number of entries that follow.
- **IP Address 1:** (4 bytes) IP of the server whose server id is in the message
- **Server id 1:** (2 bytes) Server id of a server on the network.
- **Cost 1:** Cost of the path from the server sending the update to the server whose ID is given in the packet. There would be a sequence of the last three fields.

3 Server Commands/Input Format

The server must support the following options at startup:

- `server -p <port> -t <topology-file-name> -i <routing-update-interval> -d <server-id>`
 port: Port number at which the server will run.
 topology-file-name: the topology file contains the initial topology configuration for the server
 routing-update-interval: specifies the time interval between routing updates in seconds
 server-id : id of this server

The following commands can be specified at any point during the run of the server:

- `update <Server-ID1> <Server-ID2> <Link Cost>`
 Server-ID1, Server-ID2: The link for which the cost is being updated.
 Link Cost: specifies the new link cost between the source and the destination server.
 Note that this function will be invoked at both Server-ID1 and Server-ID2 to update the cost and no other server.
- `step`
 Send routing update to neighbors (triggered/force update)

- packets
Display the number of distance vector packets this server has received since the last invocation of this information.
- display
Display the current routing table.
- disable <server id>
Disable the link to given server. To do this close all connection to the given server
- crash
Server exits, closing all connections. This is to simulate server crashes.

4 Server Responses/Output Format

The following are a list of possible responses a user can receive from a server:

- On successful execution of an update, step, packets, display or disable command, the server must display the following message:
40 <SP> <command-string> SUCCESS <CRLF>
where command string is the command executed. Additional output as desired (e.g., for display, packets, etc. commands) is specified in the previous section.
- Upon encountering an error during execution of one of these commands, the server must display the following response:
40 <SP> <command-string> <Error message> <CRLF>
where error message is a brief description of the error encountered.

<SP> denotes a space and <CRLF> is carriage return followed by line feed.
