

If we have a call

```
(map slow-function long-list)
```

where **slow-function** executes slowly and **long-list** is a large data structure, we can expect to wait quite a while for computation of the result list to complete.

Now consider **fastmap**, a version of **map** that uses futures:

```
(define (fastmap f L)
  (if (null? L)
      ()
      (cons
        (future (f (car L)))
        (fastmap f (cdr L))
      )
  )
)
```

Now look at the call

```
(fastmap slow-function long-list)
```

We will exploit a useful aspect of futures—they can be cons'd together *without delay*, even if the computation isn't completed yet.

Why? Well a **cons** just stores a pair of pointers, and it really doesn't matter what the pointers reference (a future or an actual result value).

The call to **fastmap** can actually return before *any* of the call to **slow-function** have completed:

Eventually all the futures automatically transform themselves into data values:

Note that **pcall** can be implemented using futures.

That is, instead of

```
(pcall F X Y Z)
```

we can use

```
((future F)
 (future X) (future Y) (future Z))
```

In fact the latter version is actually more parallel—execution of **F** can begin even if all the parameters aren't completely evaluated.

## ANOTHER EXAMPLE OF FUTURES

The following function, `partition`, will take a list and a data value (called `pivot`). `partition` will partition the list into two sublists:

- (a) Those elements  $\leq$  `pivot`
- (b) Those elements  $>$  `pivot`

```
(define (partition pivot L)
  (if (null? L)
      (cons () ())
      (let ((tail-part
             (partition pivot (cdr L))))
        (if (<= (car L) pivot)
            (cons
              (cons (car L) (car tail-part))
              (cdr tail-part))
            (cons
              (car tail-part)
              (cons (car L) (cdr tail-part)))
          )
        )
      )
  )
)
```

We want to add futures to `partition`, but where?

It makes sense to use a future when a computation may be lengthy and we may not need to use the value computed immediately.

What computation fits that pattern?

The computation of `tail-part`. We'll mark it in a blue box to show we plan to evaluate it using a future:

```
(define (partition pivot L)
  (if (null? L)
      (cons () ())
      (let ((tail-part
             (partition pivot (cdr L))))
        (if (<= (car L) pivot)
            (cons
              (cons (car L) (car tail-part))
              (cdr tail-part))
            (cons
              (car tail-part)
              (cons (car L) (cdr tail-part)))
          )
        )
      )
  )
)
```

But this one change isn't enough! We soon access the `car` and `cdr` of `tail-part`, which forces us to wait for its computation to complete. To avoid this delay, we can place the four references to `car` or `cdr` of `tail-part` into futures too:

```
(define (partition pivot L)
  (if (null? L)
      (cons () ())
      (let ((tail-part
             (partition pivot (cdr L))))
        (if (<= (car L) pivot)
            (cons
              (cons (car L) (car tail-part))
              (cdr tail-part))
            (cons
              (car tail-part)
              (cons (car L) (cdr tail-part)))
          )
        )
      )
  )
)
```

Now we can build the initial part of the partitioned list (that involving **pivot** and (**car L**) *independently* of the recursive call of **partition**, which completes the rest of the list.

For example,

```
(partition 17 '(5 3 8 ...))
```

creates a future (call it **future1**) to compute

```
(partition 17 '(3 8 ...))
```

It also creates **future2** to compute (**car tail-part**) and **future3** to compute (**cdr tail-part**). The call builds

## ML—META LANGUAGE

SML is *Standard ML*, a popular ML variant.

ML is a functional language that is designed to be efficient and type-safe. It demonstrates that a functional language need not use Scheme's odd syntax and need not bear the overhead of dynamic typing.

SML's features and innovations include:

1. Strong, compile-time typing.
2. Automatic *type inference* rather than user-supplied type declarations.
3. Polymorphism, including "type variables."

## 4. Pattern-directed Programming

```
fun len([]) = 0
  | len(a::b) = 1+len(b);
```

## 5. Exceptions

## 6. First-class functions

## 7. Abstract Data Types

```
coin of int |
bill of int |
check of string*real;
val dime = coin(10);
```

A good ML reference is  
 "Elements of ML Programming,"  
 by Jeffrey Ullman  
 (Prentice Hall, 1998)

## SML is INTERACTIVE

You enter a definition or expression, and SML returns a result *with* an inferred type.

The command

```
use "file name";
```

loads a set of ML definitions from a file.

For example (SML responses are in blue):

```
21;  
val it = 21 : int  
(2 div 3);  
val it = 0 : int  
true;  
val it = true : bool  
"xyz";  
val it = "xyz" : string
```

## BASIC SML PREDEFINED TYPES

### . Unit

Its only value is (). Type **unit** is similar to **void** in C; it is used where a type is needed, but no "real" type is appropriate. For example, a call to a write function may return **unit** as its result.

### . Integer

Constants are sequences of digits. Negative values are prefixed with a ~ rather than a - (- is a binary subtraction operator). For example, ~123 is negative 123.

Standard operators include

```
+ - * div mod  
< > <= >= = <>
```

### . Real

Both fractional (123.456) and exponent forms (10e7) are allowed. Negative signs and exponents use ~ rather than - (~10.0e~12).

Standard operators include

```
+ - * /  
< > <= >=
```

Note that = and <> *aren't* allowed! (Why?)

Conversion routines include  
**real(int)** to convert an **int** to a **real**,  
**floor(real)** to take the floor of a **real**,  
**ceil(real)** to take the ceiling of a **real**.

**round(real)** to round a **real**,  
**trunc(real)** to truncate a **real**.

For example, **real(3)** returns 3.0, **floor(3.1)** returns 3, **ceiling(3.3)** returns 4, **round(~3.6)** returns ~4, **trunc(3.9)** returns 3.

Mixed mode expressions, like **1 + 2.5** *aren't* allowed; you must do explicit conversion, like **real(1) + 2.5**

### . Strings

Strings are delimited by double quotes. Newlines are \n, tabs are \t, and \" and \\ escape double quotes and backslashes. E.g. "Bye now\n" The ^ operator is concatenation.

```
"abc" ^ "def" = "abcdef"
```

The usual relational operators are provided: < > <= >= = <>

## • Characters

Single characters are delimited by double quotes and prefixed by a #. For example, #`"a"` or #`"\t"`. A character *is not* a string of length one. The `str` function may be used to convert a character into a string. Thus `str("#a") = "a"`

## • Boolean

Constants are `true` and `false`. Operators include `andalso` (short-circuit and), `orelse` (short-circuit or), `not`, = and <>.

A conditional expression, (if `boolval v1` else `v2`) is available.

## Tuples

A tuple type, composed of two or more values of any type is available.

Tuples are delimited by parentheses, and values are separated by commas.

Examples include:

```
(1,2);  
val it = (1,2) : int * int  
("xyz",1=2);  
val it = ("xyz",false) :  
  string * bool  
(1,3.0,false);  
val it = (1,3.0,false) :  
  int * real * bool  
(1,2,(3,4));  
val it = (1,2,(3,4)) :  
  int * int * (int * int)
```

Equality is checked componentwise:

```
(1,2) = (0+1,1+1);
```

```
val it = true : bool
```

(1,2,3) = (1,2) causes a compile-time type error (tuples must be of the same length and have corresponding types to be compared).

#*i* selects the *i*-th component of a tuple (counting from 1). Hence

```
#2(1,2,3);
```

```
val it = 2 : int
```

## Lists

Lists are required to have a single element type for all their elements; their length is unbounded.

Lists are delimited by [ and ] and elements are separated by commas.

Thus [1,2,3] is an integer list. The empty (or null) list is [] or `nil`.

The cons operator is ::

Hence [1,2,3] ≡ 1::2::3::[]

Lists are automatically typed by ML:

```
[1,2];
```

```
val it = [1,2] : int list
```

## Cons

Cons is an infix operator represented as `::`

The left operand of `::` is any value of type  $\tau$

The right operand of `::` is any list of type  $\tau$  **list**.

The result of `::` is a list of type  $\tau$  **list**.

Hence `::` is *polymorphic*.

`[]` is the empty list. It has a type **'a list**. The symbol **'a**, read as “alpha” or “tic a” is a *type variable*.

Thus `[]` is a *polymorphic constant*.
