# **CS 538**

# Introduction to the Theory and Design of Programming Languages

Charles N. Fischer

### Spring 2008

http://www.cs.wisc.edu/~fischer/cs538.html

### CS 538 Spring 2008

# TEACHING ASSISTANT

Jongwon Yoon 3361 Computer Sciences Telephone: 608.354.3613 E-mail: yoonj@cs.wisc.edu Office Hours:

2:00 - 3:00, Mondays, Wednesdays and Fridays, or by appointment

# CLASS MEETS

Mondays, Wednesdays & Fridays, 9:55 — 10:45 1325 Computer Sciences

# INSTRUCTOR

Charles N. Fischer 6367 Computer Sciences Telephone: 608.262.6635 E-mail: fischer@cs.wisc.edu Office Hours: 10:30 - Noon, Tuesdays &

Thursdays, or by appointment

CS 538 Spring 2008

# **KEY DATES**

- Feb 25: Homework #1 (tentative)
- March 24: Programming Assignment #1 -Scheme (tentative)
- April 2: Midterm Exam (tentative)
- April 16: Programming Assignment #2 -Standard ML (tentative)
- May 2: Programming Assignment #3 -Prolog (tentative)
- May 9: Programming Assignment #4 -Java, C#, Pizza and Python
- May 15: Final Exam 2:45pm-4:45pm

# **CLASS TEXT**

Required text:

"Modern Programming Languages," Adam Webber, Franklin, Beedle & Associates, 2003.

• Handouts and Web-based reading will also be used.

# **Reading Assignment**

• Webber: Chapters 1, 10, 18 (as background)

CS 538 Spring 2008

CLASS NOTES

• Each lecture will be made available prior to that lecture on the class Web page (under the "Lecture Nodes" link).

# INSTRUCTIONAL COMPUTERS

Departmental Linux Machines (king01- king12, emperor01emperor40) have been assigned to CS 538. All necessary compiler, interpreters and tools will be loaded onto these machines.

You may also use your own PC or laptop. It will be *your* responsibility to load needed software (instructions on where to find needed software are included on the class web page).

The Systems Lab teaches brief tutorials on Linux if you are unfamiliar with that OS.

# Academic Misconduct Policy

- $\cdot$  You must do your own assignments
  - *no* copying or sharing of solutions.
- You may discuss general concepts and Ideas.
- All cases of misconduct *must* be reported to the Dean's office.
- Penalties may be severe.

CS 538 Spring 2008

# <section-header><section-header>

# Approximate Grade Weights

Homework 1	10%
Program 1 - Scheme	16%
Program 2 - ML	16%
Program 3 - Prolog	12%
Program 4 - Java, C#, Pizza and Python (optional extra credit)	10%
Midterm Exam	23%
Final Exam (non-cumulative)	23%

CS 538 Spring 2008

# Programming Languages to be Considered in Detail

1. Scheme

A modern variant of Lisp.

A *Functional Language*: Functions are "first class" data values.

*Dynamically Typed*: A variable's type may change during execution; no type declarations are needed.

All memory allocation and deallocation is *automatic*.

Primary data structures, lists and numbers, are *unlimited* in size and may grow without bound. *Continuations* provide a novel way to suspend and "re-execute" computations.

2. ML ("*M*eta *L*anguage") Strong, compile-time type checking.

Types are determined by *inference* rather than declaration.

Naturally polymorphic (one function declaration can be used with many different types).

Pattern-directed programming (you define patterns that are automatically matched during a call).

CS 538 Spring 2008

11

CS 538 Spring 2008

Typed exceptions are provided. Abstract data types, with constructors, are included.

 Prolog (*Pro*gramming in *Log*ic)
 Programs are Facts and Rules.
 Programmers are concerned with definition, not execution.
 Execution order is automatically determined.

- CS 538 Spring 2008
  - Events and delegates are included to handle asynchronous actions (like keyboard or mouse actions).
  - Properties allow user-defined read and write actions for fields.
  - Indexers allow objects other than arrays to be indexed.
  - Collection classes may be directly enumerated:
    - foreach (int i in array) ...
  - Structs and classes co-exist and may be inter-converted (boxed and unboxed).
  - Enumerations, operator overloading and rectangular arrays are provided.
  - Reference, out and variable-length parameter lists are allowed.

4. Pizza

Extends a popular Objectoriented language, Java, to include

- Parametric polymorphism (similar to C++'s templates).
- First-class functional objects.
- Algebraic data types, including patterns.
- 5. C#

Microsoft's answer to Java. In most ways it is very similar to Java, with some C++ concepts reintroduced and some useful additions.

CS 538 Spring 2008

- 6. Java 1.5 (Tiger Java, Java 5.0) Extends current definition of Java to include:
  - Parametric polymorphism (collection types may be parameterized).
  - Enhanced loop iterators.
  - Automatic boxing and unboxing of wrapper classes.
  - Typesafe enumerations.
  - Static imports (**out.println** rather than **System.out.println**).
  - · Variable argument methods.
  - Formatted output using printf: out.printf("Ans = %3d",a+b);

# Evolution of Programming Languages

### In the beginning, ...

programs were written in absolute machine code—a sequence of bits that encode machine instructions.

### Example:

34020005 0000000c 3c011001 ac220000

### This form of programming is

- Very detailed
- Very tedious
- Very error-prone
- · Very machine specific

CS 538 Spring 2008

# Symbolic Assemblers

Allow use of symbols for operation codes and labels. Example:

```
li $v0,5
syscall
sw $v0,a
```

Far more readable, but still very detailed, tedious and machine-specific.

Types are machine types.

Control structures are conditional branches.

Subprograms are blocks of code called via a "subroutine branch" instruction.

All labels are global.

# Fortran (Formula Translator)

### Example:

do 10 i=1,100

10 a(i) = 0

### Developed in the mid-50s.

### A major step forward:

- Programming became more "problem oriented" and less "machine oriented."
- Notions of control structures (ifs and do loops) were introduced.
- Subprograms, calls, and parameters were made available.
- Notions of machine independence were introduced.
- Has evolved into many new variants, including Fortran 77, Fortran 90 and HPF (High Performance Fortran).

CS 538 Sprina 2008

20

# **Cobol (***Co*mmon *B*usiness *O*riented *L*anguage**)**

# Example:

multiply i by 3 giving j.
move j to k.
write line1 after advancing
1 lines.

Developed in the early 60s.

The first widely-standardized programming language. Once dominant in the business

world; still important.

Wordy in structure; designed for non-scientific users.

Raised the issue of who should program and how important readability and maintainability are.

### CS 538 Spring 2008

# Algol 60 (Algorithmic Language)

# Example:

```
real procedure cheb(x,n);
value x,n;
real x; integer n;
cheb :=
    if n = 0 then 1
    else if n = 1 then x
    else 2 x x x
    cheb(x,n-1)-cheb(x,n-2);
Developed about 1960.
```

A direct precursor of Pascal, C, C++ and Java.

Introduced many ideas now in wide use:

- Blocks with local declarations and scopes.
- Nested declarations and control structures.

CS 538 Spring 2008

21

- Parameter passing
- Automatic recursion.

### But,

- I/O wasn't standardized.
- IBM promoted Fortran and PL/I.

# Lisp (List Processing Language)

# Example:

((lambda (x) (\* x x)) 10)

Developed in the early 60s.

A radical departure from earlier programming languages.

Programs and data are represented in a *uniform* list format.

Types are a property of data values, *not* variables or parameters.

A program can build and run new functions as it executes.

Data values were not fixed in size.

23

Memory management was automatic.

A *formal semantics* was developed to define precisely what a program means.

# Simula 67 (Simulation Algol)

### Example:

Class Rectangle (Width, Height); Real Width, Height; Boolean Procedure IsSquare; IsSquare := Width=Height; End of Rectangle;

Developed about 1967.

Introduced the notion of a class (for simulation purposes).

Included *objects*, a garbage collector, and notions of extending a class.

C++ was originally C with classes (as Simula was Algol with classes).

CS 538 Spring 2008

25

CS 538 Spring 2008

# C and C++

C was developed in the early 70's; C++ in the mid-80s.

These languages have a concise, expressive syntax; they generate high quality code sufficient for performance-critical applications.

C, along with Unix, proved the viability of *platformindependent* languages and applications.

C and C++ allow programmers a great deal of freedom in bending and breaking rules.

Raises the issue of whether one language can span both novice and expert programmers.

Interesting issue—if most statements and expressions are meaningful, can errors be readily detected?

if (a=b) a=0; else a = 1;

CS 538 Spring 2008

27

# Java

Developed in the late 90s.

Cleaner object-oriented language than C++.

Introduced notions of dynamic loading of class definitions across the Web.

Much stronger emphasis on secure execution and detection of run-time errors.

Extended notions of platform independence to system independence.

# What Drives Research into New Programming Languages?

### Why isn't C or C++ or C+++ enough?

1. Curiosity

CS 538 Spring 2008

What other forms can a programming language take? What other notions of programming are possible?

 Productivity
 Procedural languages, including C, C++ and Java, are very detailed.

Many source lines imply significant development and maintenance expenses.

CS 538 Spring 2008

29

3. Reliability

Too much low-level detail in programs greatly enhances the chance of minor errors. Minor errors can raise significant problems in applications.

4. Security

Computers are entrusted with great responsibilities. How can we know that a program is safe and reliable enough to trust?

# 5. Execution speed

Procedural languages are closely tied to the standard sequential model of instruction execution. We may need radically different programming models to fully exploit parallel and distributed computers.

# Desirable Qualities in a Programming Language

Theoretically, all programming languages are equivalent (Why?)

If that is so, what properties are desirable in a programming language?

 $\cdot$  It should be easy to use.

Programs should be easy to read and understand.

Programs should be simple to write, without subtle pitfalls.

It should be *orthogonal*, providing only one way to do each step or computation.

Its notation should be natural for the application being programed.

31

CS 538 Sprina 2008

# Programming languages

naturally fall into a number of fundamental styles or *paradigms*.

### **Procedural Languages**

Most of the widely-known and widely-used programming languages (C, Fortran, Pascal, Ada, etc.) are *procedural*.

Programs execute statement by statement, reading and modifying a shared memory.

This programming style closely models conventional sequential processors linked to a random access memory (RAM). Question: Given a = a + 1; if (a > 10

if (a > 10) b = 10; else b = 15; a = a \* b;

Why can't 5 processors each execute one line to make the program run 5 times faster?

CS 538 Spring 2008

### **Functional Languages**

Lisp, Scheme and ML are *functional* in nature.

Programs are expressions to be evaluated.

Language design aims to *minimize* side-effects, including assignment.

Alternative evaluation mechanisms are possible, including

**Lazy** (Demand Driven)

Eager (Data Driven or Speculative)

### CS 538 Spring 2008

### 37

Subclassing allows to you extend or redefine part of an object's behavior without reprogramming all of the object's definition. Thus in Java, you can take a Hashtable class (which is fairly elaborate) and create a subclass in which an existing method (like tostring) is redefined, or new operations are added.

### **Object-Oriented Languages**

C++, Java, Smalltalk, Pizza and Python are object-oriented.

Data and functions are encapsulated into Objects.

Objects are active, have persistent state, and uniform interfaces (messages or methods).

Notions of inheritance and common interfaces are central.

All objects that provide the same interface are treated uniformly. In Java you can print any object that provides the tostring method. Iteration through the elements of any object that implements the Enumeration interface is possible.

CS 538 Spring 2008

### Logic Programming Languages

Prolog notes that most programming languages address both the logic of a program (what is to be done) and its control flow (how you do what you want).

A logic programming language, like Prolog, lets programmers focus on a program's logic without concern for control issue.

These languages have no real control structures, and little notion of "flow of control."

What results are programs that are unusually succinct and focused.

### Example:

This is a *complete*, *executable* function that determines if a list is in order. It is naturally polymorphic, and is not cluttered with declarations, variables or explicit loops.

CS 538 Spring 2008

# Review of Concepts from Procedural Programming Languages

Declarations/Scope/Lifetime/ Binding

Static/Dynamic

- Identifiers are *declared*, either explicitly or implicitly (from context of first use).
- Declarations *bind* type and kind information to an identifier. Kind specifies the grouping of an identifier (variable, label, function, type name, etc.)
- Each identifier has a *scope* (or range) in a program—that part of the program in which the identifier is visible (i.e., may be used).

CS 538 Spring 2008

41

- Data objects have a *lifetime*—the span of time, during program execution, during which the object exists and may be used.
- Lifetimes of data objects are often tied to the scope of the identifier that denotes them. The objects are created when its identifier's scope is entered, and they may be deleted when the identifier's scope is exited. For example, memory for local variables within a function is usually allocated when the function is called (activated) and released when the call terminates. In Java, a method may be loaded into memory when the object it is a member of is first accessed.

Properties of an identifier (and the object it represents) may be set at

### Compile-time

These are *static* properties as they do not change during execution. Examples include the type of a variable, the value of a constant, the initial value of a variable, or the body of a function.

### • Run-time

These are *dynamic* properties. Examples include the value of a variable, the lifetime of a heap object, the value of a function's parameter, the number of times a while loop iterates, etc.

# Example:

### In Fortran

- The scope of an identifier is the whole program or subprogram.
- Each identifier may be declared only once.
- Variable declarations may be implicit. (Using an identifier implicitly declares it as a variable.)
- The lifetime of data objects is the whole program.

45

CS 538 Spring 2008

# Block Structured Languages

- Include Algol 60, Pascal, C and Java.
- Identifiers may have a non-global scope. Declarations may be *local* to a class, subprogram or block.
- Scopes may *nest*, with declarations propagating to inner (contained) scopes.
- The lexically *nearest* declaration of an identifier is bound to uses of that identifier.

CS 538 Spring 2008

Binding of an identifier to its corresponding declaration is usually static (also called lexical), though dynamic binding is also possible.

Static binding is done prior to execution—at compile-time. Example (drawn from C):

# **Block Structure Concepts**

- Nested Visibility
   No access to identifiers outside
- their scope.Nearest Declaration Applies

Static name scoping.

 Automatic Allocation and Deallocation of Locals

Lifetime of data objects is bound to the scope of the Identifiers that denote them.

```
Variations in these rules of
name scoping are possible.
For example, in Java, the
lifetime of all class objects is
from the time of their creation
(via new) to the last visible
reference to them.
Thus
... Object O;...
creates an object reference but
does not allocate any memory
```

space for o.

You need

... Object O = new Object(); ...

to actually create memory space for o.

# **Dynamic Scoping**

An alternative to static scoping is dynamic scoping, which was used in early Lisp dialects (but not in Scheme, which is statically scoped).

Under dynamic scoping. identifiers are bound to the dvnamicallv closest declaration of the identifier. Thus if an identifier is not locally declared, the call chain (sequence of callers) is examined to find a matching declaration.

CS 538 Spring 2008

CS 538 Spring 2008

49

# Example:

```
int x;
void print() {
  write(x); }
main () {
  bool x;
  print();
```

}

Under static scoping the x written in print is the lexically closest declaration of x, which is as an int.

Under dynamic scoping, since print has no local declaration of x, print's caller is examined. Since main calls print, and it has a declaration of x as a bool, that declaration is used.

Dynamic scoping makes type checking and variable access harder and more costly than static scoping. (Why?)

However, dynamic scoping does allow a notion of an "extended scope" in which declarations extend to subprograms called within that scope.

Though dynamic scoping may seen a bit bizarre, it is closely related to virtual functions used in C++ and Java.

51

# Virtual Functions

A function declared in a class, C, may be redeclared in a class derived from C. Moreover, for uniformity of redeclaration, it is important that *all* calls, including those in methods within C, use the new declaration.

### Example:

CS 538 Spring 2008

```
class C {
  void DoIt()(PrintIt();}
  void PrintIt()
    {println("C rules!");}
}
class D extends C {
  void PrintIt()
    {println("D rules!");}
  void TestIt() {DoIt();}
}
D dvar = new D();
dvar.TestIt();
D rules! is printed.
```

# Scope vs. Lifetime

It is usually required that the lifetime of a run-time object at least cover the scope of the identifier. That is, whenever you can access an identifier, the run-time object it denotes better exist.

### But,

it is possible to have a run-time object's lifetime *exceed* the scope of its identifier. An example of this is *static* or *own* variables.

CS 538 Spring 2008

53

In C: void p() { static int i = 0; print(i++); 3 Each call to  $\mathbf{p}$  prints a different value of i (0, 1, ...) Variable i retains its value across calls. Some languages allow an explicit binding of an identifier for a fixed scope: Let id = val type id = val; in statements statements } end; A declaration may appear wherever a statement or expression is allowed. Limited scopes enhance readability.

# STRUCTS VS. Blocks

Many programming languages, including C, C++, C#, Pascal and Ada, have a notion of grouping data together into *structs* or *records*.

### For example:

struct complex { float re, im; }
There is also the notion of
grouping statements and
declarations into blocks:

{ float re, im; re = 0.0; im = 1.0; }

55

### Blocks and structs look similar, but there are significant differences:

Structs are data,

- As originally designed, structs contain only data (no functions or methods).
- Structs can be dynamically created, in any number, and included in other data structures (e.g., in an array of structs).
- All fields in a struct are visible outside the struct.

Blocks are *code*,

- They can contain both code and data.
- Blocks *can't* be dynamically created during execution; they are "built into" a program.
- Locals in a block *aren't* visible outside the block.

By adding functions and initialization code to structs, we get *classes*—a nice blend of structs and blocks.

### For example:

### class complex{

```
float re, im;
complex (float v1, float v2){
  re = v1; im = v2; }
```

```
}
```

CS 538 Spring 2008

CS 538 Spring 2008

57

# CLASSES

- Class objects can be created as needed, in any number, and included in other data structure.
- They include both data (fields) and functions (methods).
- They include mechanisms to initialize themselves (constructors) and to finalize themselves (destructors).
- They allow controlled access to members (private and public declarations).

# Type Equivalence in Classes

In C, C++ and Java, instances of the same struct or class are type-equivalent, and mutually assignable.

For example:

class MyClass { ... }
MyClass v1, v2;
v1 = v2; // Assignment is OK

We expect to be able to assign values of the same type, including class objects.

However, sometimes a class models a data object whose size or shape is set upon creation (in a constructor).

# Then we may *not* want assignment to be allowed.

```
class Point {
    int dimensions;
    float coordinates[];
    Point () {
        dimensions = 2;
        coordinates = new float[2];
    }
    Point (int d) {
        dimensions = d;
        coordinates = new float[d];
    }
}
Point plane = new Point();
Point solid = new Point(3);
plane = solid; //OK in Java
```

This assignment is allowed, even though the two objects represent points in different dimensions.

CS 538 Spring 2008

# Subtypes

In C++, C# and Java we can create *subclasses*—new classes derived from an existing class.

We can use subclasses to create new data objects that are similar (since they are based on a common parent), but still *type-inequivalent*.

Example:

```
class Point2 extends Point {
    Point2() {super(2); }
}
class Point3 extends Point {
    Point3() {super(3); }
}
Point2 plane = new Point2();
Point3 solid = new Point3();
plane = solid; //Illegal in Java
```

CS 538 Spring 2008

61

62

# **PARAMETRIC POLYMORPHISM**

We can create distinct subclasses based on the values passed to constructors. But sometimes we want to create subclasses based on distinct *types*, and types can't be passed as parameters. (Types are not values, but rather a **property** of values.)

We see this problem in Java, which tries to create general purpose data structures by basing them on the class object. Since any object can be assigned to object (all classes must be a subclass of object), this works—at least partially.

```
class LinkedList {
  Object value;
  LinkedList next;
  Object head() {return value;}
 LinkedList tail(){return next;}
 LinkedList(Object 0) {
     value = 0; next = null;}
  LinkedList(Object 0,
             LinkedList L) {
     value = 0; next = L;}
}
Using this class, we can create
a linked list of any subtype of
Object.
But,
• We can't guarantee that linked lists
 are type homogeneous (contain
 only a single type).
```

• We must cast **Object** types back into their "real" types when we extract list values.

• We must use wrapper classes like Integer rather than int (because primitive types like int aren't objects, and aren't subclass of Object).

For example, to use **LinkedList** to build a linked list of **int**s we do the following:

```
LinkedList 1 =
   new LinkedList(new Integer(123));
int i =
   ((Integer) l.head()).intValue();
```

This is pretty clumsy code. We'd prefer a mechanism that allows us to create a "custom version" of LinkedList, based on the type we want the list to contain.

```
CS 538 Spring 2008
```

We can't just call something like LinkedList(int) Or LinkedList(Integer) because types can't be passed as parameters.

Parametric polymorphism is the solution. Using this mechanism, we can use type parameters to build a "custom version" of a class from a general purpose class.

C++ allows this using its template mechanism. Tiger Java also allows type parameters.

In both languages, type parameters are enclosed in "angle brackets" (e.g., LinkedList<T> passes T, a type, to the LinkedList class).

CS 538 Spring 2008

65

```
Thus we have
class LinkedList<T> {
  T value; LinkedList<T> next;
  T head() {return value;}
  LinkedList<T> tail() {
    return next;}
  LinkedList(T O) {
    value = 0; next = null;}
  LinkedList(T O,LinkedList<T> L)
    {value = 0; next = L;}
}
LinkedList<int> 1 =
    new LinkedList(123);
int i = 1.head();
```

# Overloading and Ad-hoc Polymorphism

Classes usually allow overloading of method names, if only to support multiple constructors.

That is, more than one method definition with the same name is allowed within a class, as long as the method definitions differ in the number and/or types of the parameters they take.

```
For example,
```

CS 538 Sprina 2008

```
class MyClass {
    int f(int i) { ... }
    int f(float g) { ... }
    int f(int i, int j) { ... }
}
```

Overloading is sometimes called "ad hoc" polymorphism, because, to the programmer, it appears that one method can take a variety of different parameter types. This isn't true polymorphism because the methods have different bodies; there is no sharing of one definition among different parameter types. There is no guarantee that the different definitions do the same thing, even though they share a common name.

### CS 538 Spring 2008

# Why is this form of overloading usually disallowed?

It's because overload resolution (deciding which definition to use) becomes much harder. Consider

```
class MyClass {
   int f(int i, int j) { ... }
   float f(float i, float j) { ... }
   float f(int i, int j) { ... }
}
```

```
in
```

```
int a = f( f(1,2), f(3,4) );
which definitions of f do we
use in each of the three calls?
Getting the correctly answer
can be tricky, though solution
algorithms do exist.
```

# Issues in Overloading

Though many languages allow overloading, few allow overloaded methods to differ only on their result types. (Neither C++ nor Java allow this kind of overloading, though Ada does). For example,

```
class MyClass {
    int f() { ... }
    float f() { ... }
```

# }

is illegal. This is unfortunate; methods with the same name and parameters, but different result types, could be used to automatically convert result values to the type demanded by the context of call.

```
CS 538 Spring 2008
```

69

### **Operator Overloading**

Some languages, like C++ and C#, allow operators to be overloaded. You may add new definitions to existing operators, and use them on your own types. For example,

```
class MyClass {
    int i;
    public:
        int operator+(int j) {
            return i+j; }
}
MyClass c;
int i = c+10;
int j = c.operator+(10);
int k = 10+c; // Illegal!
```

The expression 10+c is illegal because there is no definition of + for the types int and Myclass&. We can create one by using C++'s *friend* mechanism to insert a definition into Myclass that will have access to Myclass's private data:

```
class MyClass {
    int i;
    public:
        int operator+(int j) {
            return i+j; }
    friend int operator+
        (int j, MyClass& v){
            return j+v.i; }
}
MyClass c;
int k = 10+c; // Now OK!
```

C++ limits operator overloading to existing predefined operators. A few languages, like Algol 68 (a successor to Algol 60, developed in 1968), allow programmers to define brand new operators. In addition to defining the operator itself, it is also necessary to specify the operator's precedence (which operator is to be applied first) and its associativity (does the operator associate from left to right, or right to left, or not at all). Given this extra detail, it is possible to

op +++ prec = 8; int op +++(int& i, int& j) {
 return (i++)+(j++); }

specify something like

(Why is **int** used as the parameter type rather than **int**?)

CS 538 Spring 2008

# PARAMETER BINDING

Almost all programming languages have some notion of *binding* an *actual parameter* (provided at the point of call) to a *formal parameter* (used in the body of a subprogram).

There are many different, and inequivalent, methods of parameter binding. Exactly which is used depends upon the programming language in question.

Parameter Binding Modes include:

• Value: The formal parameter represents a local variable initialized to the value of the corresponding actual parameter.

- Result: The formal parameter represents a local variable. Its final value, at the point of return, is copied into the corresponding actual parameter.
- Value/Result: A combination of the value and results modes. The formal parameter is a local variable initialized to the value of the corresponding actual parameter. The formal's final value, at the point of return, is copied into the corresponding actual parameter.
- Reference: The formal parameter is a pointer to the corresponding actual parameter. All references to the formal parameter indirectly access the corresponding actual parameter through the pointer.

75

CS 538 Spring 2008

73

- Name: The formal parameter represents a block of code (sometimes called a *thunk*) that is evaluated to obtain the value or address of the corresponding actual parameter. Each reference to the formal parameter causes the thunk to be reevaluated.
- Readonly (sometimes called Const): Only reads of the formal parameter are allowed. Either a copy of the actual parameter's value, or its address, may be used.

CS 538 Spring 2008

# Example

### What element of $\mathbf{k}$ is printed?

- The assignment to a does not affect i, since a is a value parameter.
- The assignment to **b** *does* affect **j**, since **b** is a reference parameter.
- c is a name parameter, so it is evaluated whenever it is used. In the print statement k[i][j] is printed. At that point i=3 and j=2, so k[3][2] is printed.

# What Parameter Modes do Programming Languages Use?

- C: Value mode except for arrays which pass a pointer to the start of the array.
- C++: Allows reference as well as value modes. E.g.,

int f(int a, int& b)

- C#: Allows result (out) as well as reference and value modes. E.g., int g(int a, out int b)
- Java: Scalar types (int, float, char, etc.) are passed by value; objects are passed by reference (references to objects are passed by value).
- Fortran: Reference (even for constants!)
- Ada: Value/result, reference, and readonly are used.

CS 538 Spring 2008

77

Why are there so Many Different Parameter Modes?

Parameter modes reflect different views on how parameters are to be accessed, as well as different degrees of efficiency in accessing and using parameters.

- Call by value *protects* the actual parameter value. No matter what the subprogram does, the parameter *can't* be changed.
- Call by reference allows *immediate* updates to the actual parameter.
- Call by readonly protects the actual parameter and emphasizes the "constant" nature of the formal parameter.

- Call by value/result allows actual parameters to change, but treats a call as a single step (assign parameter values, execute the subprogram's body, update parameter values).
- Call by name delays evaluation of an actual parameter until it is actually needed (which may be never).

### CS 538 Spring 2008

# Call by NAME

Call by name is a special kind of parameter passing mode. It allows some calls to complete that otherwise would fail. Consider

f(i,j/0)

Normally, when j/o is evaluated, a *divide fault* terminates execution. If j/o is passed by name, the division is delayed until the parameter is needed, which may be never.

Call by name also allows programmers to create some interesting solutions to hard programming problems.

Consider the conditional expression found in C, C++,

```
and Java:
(cond ? value1 : value2)
```

```
What if we want to implement this as a function call:
```

```
condExpr(cond,value1,value2) {
  if (cond)
     return value1;
  else return value2;
```

```
}
```

With most parameter passing modes this implementation *won't work*! (Why?)

But if value1 and value2 are passed by name, the implementation is correct.

# Call by Name and Lazy Evaluation

Call by name has much of the flavor of *lazy evaluation*. With lazy evaluation, you don't compute a value but rather a *suspension*—a function that will provide a value when called.

This can be useful when we need to control how much of a computation is actually performed.

Consider an infinite list of integers. Mathematically it is represented as

1, 2, 3, ...

How do we compute a data structure that represents an infinite list?

83

CS 538 Spring 2008

81

```
The obvious computation
                                                          The whole list is there, but only as
                                                          much as you care to access is
      infList(int start) {
                                                          actually computed.
        return list(start,
                  infList(start+1));
      }
    doesn't work. (Why?)
    A less obvious implementation,
    using suspensions, does work:
    infList(int start) {
        return list(start,
          function() {
           return infList(start+1);
          });
    }
    Now, whenever we are given an
    infinite list, we get two things: the
    first integer in the list and a
    suspension function. When called,
    this function will give you the rest
    of the infinite list (again, one
    more value and another
    suspension function).
CS 538 Spring 2008
                                                     CS 538 Spring 2008
                                           85
```

### **EAGER PARAMETER EVALUATION**

Sometimes we want parameters evaluated *eagerly*—as soon as they are known.

Consider a sorting routine that breaks an array in half, sorts each half, and then merges together the two sorted halves (this is a *merge sort*).

In outline form it is: sort(inputArray) {

• • •

again be split in two, allowing parallel sorting of four quartersized arrays, then leading to 8 sorts of 1/8 sized arrays, etc.

### But,

to make this all work, the two parameters to merge must be evaluated *eagerly*, rather than in sequence.

# Type Equivalence

Programming languages use types to describe the values a data object may hold and the operations that may be performed.

By checking the types of values, potential errors in expressions, assignments and calls may be automatically detected. For example, type checking tells us that

123 + "123"

is illegal because addition is not defined for an integer, string combination.

Type checking is usually done at compile-time; this is *static typing*.

CS 538 Spring 2008

89

The question reduces to whether the programming language allows programmers to "break" the type rules, either knowingly or unknowingly.

Java is strongly typed; type errors preclude execution. C and C++ are weakly typed; you can break the rules if you wish. For example:

int i; int\* p;

```
p = (int *) i * i;
```

Now **p** may be used as an integer pointer though multiplication need not produce valid integer pointers.

If we are going to do type checking in a program, we must decide whether two types, T1 and T2 are equivalent; that is, whether they be used interchangeably. Type-checking may also be done at run-time; this is *dynamic typing*.

A program is *type-safe* if it is impossible to apply an operation to a value of the wrong type. In a type-safe language, plus is never told to add an integer to a string, because its definition does not allow that combination of operands. In type-safe programs an operator can still see an illegal value (e.g., a division by zero), but it can't see operands of the wrong type.

A *strongly-typed* programming language forbids the execution of type-unsafe programs.

*Weakly-typed* programming languages allow the execution of potentially type-unsafe programs.

CS 538 Spring 2008

There are two major approaches to type equivalence:

Name Equivalence:

Two types are equivalent if and only if they refer to exactly the same type declaration.

For example,

type PackerSalaries = int[100]; type AssemblySizes = int[100]; PackerSalaries salary; AssemblySizes size;

ls

sal = size; allowed?

Using name equivalence, *no*. That is, **salary**  $\neq_N$  **size** since these two variables have different type declarations (that happen to be identical in structure).

```
Formally, we define \equiv_{N} (name type
     equivalence) as:
     (a) T ≡<sub>N</sub> T
     (b) Given the declaration
          Type T1 = T2;
         T1 ≡<sub>N</sub> T2
     We treat anonymous types (types
     not given a name) as an
     abbreviation for an implicit
     declaration of a new and unique
     type name.
     Thus
       int A[10];
     is an abbreviation for
       Type T<sub>new</sub> = int[10];
       T<sub>new</sub> A;
CS 538 Spring 2008
                                                93
```

# STRUCTURAL EQUIVALENCE

An alternative notion of type equivalence is structural equivalence (denoted  $\equiv_S$ ). Roughly, two types are structurally equivalent if the two types have the same definition, independent of where the definitions are located. That is, the two types have the same definitional structure.

Formally,

(a) T ≡<sub>S</sub> T

CS 538 Spring 2008

(b) Given the declaration

(c) If T and Q are defined using the same type constructor and corresponding parameters in the

two definitions are equal or structurally equivalent then  $T \equiv_S Q$ 

```
Returning to our previous
example,
type PackerSalaries = int[100];
type AssemblySizes = int[100];
PackerSalaries salary;
AssemblySizes size;
```

**salary**  $\equiv_S$  **size** since both are arrays and **100=100** and **int**  $\equiv_S$  **int**.

# Which notion of Equivalence do Programming Languages Use?

C and C++ use structural equivalence except for structs and classes (where name equivalence is used). For arrays, size is ignored.

Java uses structural equivalence for scalars. For arrays, it requires name equivalence for the component type, ignoring size. For classes it uses name equivalence except that a subtype may be used where a parent type is expected. Thus given

void subr(Object 0) { ... };
the call

subr(new Integer(100));
is OK since Integer is a subclass of
Object.

5

# **AUTOMATIC Type Conversions**

C, C++ and Java also allow various kinds of automatic type conversions.

In C, C++ and Java, a **float** will be automatically created from an **int**:

float f = 10; // No type error
Also, an integer type (char,
short, int, long) will be
widened:

int i = 'x'; In C and C++ (but not Java), an integer value can also be narrowed, possibly with the loss of significant bits: char c = 1000000;

   (linked from class web page)

CS 538 Spring 2008

97

# Lisp & Scheme

Lisp (*List P*rocessing Language) is one of the oldest programming languages still in wide use.

It was developed in the late 50s and early 60s by John McCarthy.

Its innovations include:

- Support of symbolic computations.
- A *functional programming style* without emphasis on assignments and side-effects.
- A naturally recursive programming style.
- Dynamic (run-time) type checking.

- Dynamic data structures (lists, binary trees) that grow without limit.
- Automatic garbage collection to manage memory.
- Functions are treated as "first class" values; they may be passed as arguments, returned as result values, stored in data structures, and created during execution.
- A formal semantics (written in Lisp) that defines the meaning of all valid programs.
- An Integrated Programming Environment to create, edit and test Lisp programs.

# Scheme

Scheme is a recent dialect of Lisp.

It uses lexical (static) scoping. It supports true first-class

functions. It provides program-level

access to control flow via *continuation* functions.

### CS 538 Spring 2008

### 101

# Reals:

A floating point number in a decimal format (**123.456**) or in exponential format (**1.23e45**). A leading sign and a signed exponent are allowed (-**12.3**, **10.0e-20**).

### Rationals:

Rational numbers of the form integer/integer (e.g., 1/3 or 9/7) with an optional leading sign (-1/ 2, +7/8).

### Complex:

Complex numbers of the form num+num i or num-num i, where num is an integer or real number. Example include 1+3i, -1.5-2.5i, 0+1i).

# ATOMIC (PRIMITIVE) DATA TYPES

### Symbols:

Essentially the same form as identifiers. Similar to enumeration values in C and C++.

Very flexible in structure; essentially any sequence of printable characters is allowed; anything that starts a valid number (except + or -) *may not* start a symbol.

Valid symbols include:

abc hello-world + <=!

### Integers:

Any sequence of digits, optionally prefixed with a + or -. Usually unlimited in length.

CS 538 Spring 2008

### String:

A sequence of characters delimited by double quotes. Double quotes and backslashes must be escaped using a backslash. For example

"Hello World" "\"Wow!\""

### Character:

A single character prefixed by #\. For example, #\a, #\0, #\\, #\#. Two special characters are #\space and #\newline.

### Boolean:

True is represented as **#t** and false is represented as **#f**.

### Lists

# FUNCTION CALLS

CS 538 Spring 2008

In List and Scheme, function calls are represented as lists.

(A B C) means:

Evaluate **A** (to a function)

Evaluate **B** and **C** (as parameters) Call **A** with **B** and **C** as its

parameters

Use the value returned by the call as the "meaning" of (**A B C**).

**cons, car** and **cdr** are predefined symbols bound to built-in functions that build and access lists and S-Expressions.

Literals (of type integer, real, rational, complex, string, character and boolean) evaluate to themselves.

107

```
Thus (quote (1 2)) doesn't try
to evaluate the list (1 2); it just
returns it.
Since quotation is so often used,
it may be abbreviated using a
single quote. That is
(quote arg) \equiv 'arg
Thus
(car '(a b c)) \Rightarrow a
(cdr '((A) (B) (C))) \Rightarrow
((B) (C) )
(cons 'a '1) \Rightarrow (a . 1)
But,
('cdr '(A B)) fails!
Why?
```

```
CS 538 Spring 2008
```

# **User-defined Functions**

The list

(lambda (args) (body)) evaluates to a function with (args) as its argument list and (body) as the function body. No quotes are needed for

(args) Of (body).

Thus

(lambda (x) (+ x 1)) evaluates to the increment function.

Similarly,

 $\begin{array}{ccc} ((\texttt{lambda} (\texttt{x}) (\texttt{+ x 1})) & \texttt{10}) \Rightarrow \\ \texttt{11} \end{array}$ 

We can bind values and functions to global symbols using the define function.

The general form is

(define id object)

ia is not evaluated but object is. ia is bound to the value object evaluates to.

For example,

(define pi 3.1415926535)

(define plus1
 (lambda (x) (+ x 1)) )

(define pi\*2 (\* pi 2)) Once a symbol is defined, it evaluates to the value it is bound to:

(plus1 12)  $\Rightarrow$  13

CS 538 Spring 2008

109

```
Since functions are frequently
defined, we may abbreviate
(define id
    (lambda (args) (body)) )
as
    (define (id args) (body) )
Thus
    (define (plus1 x) (+ x 1))
```

```
Conditional Expressions in Scheme
```

A *predicate* is a function that returns a boolean value. By convention, in Scheme, predicate names end with "?"

For example,

number? symbol? equal? null? list? In conditionals, #f is false, and

everything else, including #t, is true.

The **if** expression is

(if pred E1 E2)

First **pred** is evaluated. Depending on its value (**#f** or not), either **E1** or **E2** is evaluated (but not both) and returned as the value of the **if** expression.

For example, (if (= 1 (+ 0 1)) 'Yes 'No ) (define (fact n) (if (= n 0) 1 (\* n (fact (- n 1))) ) ) CS 538 Spring 2008<sup>®</sup>

113

### **RECURSION IN SCHEME** Thus (cons '(a b) '(c d)) $\Rightarrow$ Recursion is widely used in ((a b) c d) Scheme and most other functional $(append '(a b) '(c d)) \Rightarrow$ programming languages. (a b c d)The **append** function is predefined Rather than using a loop to step in Scheme, as are many other through the elements of a list or useful list-manipulating functions array, recursion breaks a problem (consult the Scheme definition for on a large data structure into a what's available). simpler problem on a smaller data It is instructive to define **append** structure. directly to see its recursive A good example of this approach approach: is the **append** function, which (define joins (or appends) two lists into (append L1 L2) one larger list containing all the (if (null? L1) elements of the two input lists (in T.2 the correct order). (cons (car L1) (append (cdr L1) L2)) Note that **cons** is not **append**. ) cons adds one element to the ) head of an existing list. CS 538 Spring 2008 CS 538 Spring 2008 117

Let's trace (append '(a b) '(c d)) Our definition is (define (append L1 L2) (if (null? L1) г5 (cons (car L1) (append (cdr L1) L2)) ) ) Now L1 = (a b) and L2 = (c d). (null? L1) is false, so we evaluate (cons (car L1) (append (cdr L1) L2)) = (cons (car '(a b)) (append (cdr '(a b)) '(c d))) = (cons 'a (append '(b) '(c d))We need to evaluate (append '(b) '(c d))In this call, L1 = (b) and L2 = (c d). L1 is not null, so we evaluate

```
(cons (car L1) (append (cdr L1) L2))
= (cons (car '(b)))
        (append (cdr '(b)) '(c d)))
= (cons 'b (append '() '(c d))
We need to evaluate
 (append '() '(c d))
In this call, L1 = () and L2 = (c d).
L1 is null, so we return (c d).
Therefore
(cons 'b (append '() '(c d)) =
(cons 'b '(c d)) = (b c d) =
(append '(b) '(c d))
Finally.
(append '(a b) '(c d)) =
(cons 'a (append '(b) '(c d)) =
(cons 'a '(b c d)) = (a b c d)
Note:
Source files for append, and other
Scheme examples, are in
~cs538-1/public/scheme/example1.scm,
~cs538-1/public/scheme/example2.scm,
etc.
```

```
As an example, consider
(rev '(1 2))
Here L = (1 \ 2). L is not null so we
evaluate
(append (rev (cdr L))
               (list (car L))) =
(append (rev (cdr '(1 2)))
               (list (car '(1 2)))) =
(append (rev '(2)) (list 1)) =
(append (rev '(2)) '(1))
We must evaluate (rev (2))
Here \mathbf{L} = (2). \mathbf{L} is not null so we
evaluate
(append (rev (cdr L))
               (list (car L))) =
(append (rev (cdr '(2)))
               (list (car '(2)))) =
(append (rev ())(list 2)) =
(append (rev ())'(2))
We must evaluate (rev ())
Here \mathbf{L} = (). \mathbf{L} is null so
 (rev '())= ()
```

CS 538 Spring 2008

Thus (append (rev ())'(2)) = (append ()'(2)) = (2) = (rev '(2)) Finally, recall (rev '(1 2)) = (append (rev '(2))'(1)) = (append '(2)'(1)) = (2 1) As constructed, rev only reverses the "top level" elements of a list. That is, members of a list that themselves are lists *aren't* reversed.

For example,

(rev '( (1 2) (3 4))) =

((3 4) (1 2))

We can generalize **rev** to also reverse list members that happen to be lists.

To do this, it will be convenient to use Scheme's **let** construct.

# THE LET CONSTRUCT

Scheme allows us to create local names, bound to values, for use in an expression.

The structure is

(let ( (id1 val1) (id2 val2) ... )
 expr )

In this construct, **val1** is evaluated and bound to **id1**, which will exist only within this **let** expression. If **id1** is already defined (as a global or parameter name) the existing definition is hidden and the local definition, bound to **val1**, is used. Then **val2** is evaluated and bound to **id2**, .... Finally, **expr** is evaluated in a scope that includes **id1**, **id2**, ....

123

```
For example,
     (let ( (a 10)
                        (b 20) )
       (+ a b)) \Rightarrow 30
     Using a let, the definition of
     reval1, a version of rev that
     reverses all levels of a list, is easy:
     (define (revall L)
       (if (null? L)
           ь
           (let ((E (if (list? (car L))
                       (revall (car L))
                       (car L) )))
             (append (revall (cdr L))
                       (list E))
           )
      )
     )
     (revall '( (1 2)
                             (3 4))) \Rightarrow
      ((4 3) (2 1))
CS 538 Spring 2008
                                             125
```

```
Subsets
```

Another good example of Scheme's recursive style of programming is subset computation.

Given a list of distinct atoms, we want to compute a list of all subsets of the list values.

For example,

The order of atoms and sublists is unimportant, but all possible subsets of the list values must be included.

Given Scheme's recursive style of programming, we need a recursive definition of subsets.

CS 538 Spring 2008

That is, if we have a list of all subsets of n atoms, how do we extend this list to one containing all subsets of n+1 values? First, we note that the number of subsets of n+1 values is exactly *twice* the number of subsets of n values. For example, (subsets '(1 2))  $\Rightarrow$ (() (1) (2) (1 2)), which contains 4 subsets.

(subsets '(1 2 3)) contains 8 subsets (as we saw earlier).

Moreover, the extended list (of subsets for n+1 values) is simply the list of subsets for n values *plus* the result of "distributing" the new value into each of the original subsets.

```
Thus (subsets '(1 2 3)) \Rightarrow
( () (1) (2) (3) (1 2) (1 3)
(2 3) (1 2 3)) =
( ()
       (1)
             (2)
                   (1 2) ) plus
((3)(13)(23)(123))
This insight leads to a concise
program for subsets.
We will let (distrib L E) be a
function that "distributes" E into
each list in L.
For example,
(distrib '(() (1) (2) (1 2)) 3) =
((3)(31)(32)(312))
(define (distrib L E)
  (if (null? L)
      ()
      (cons (cons E (car L))
            (distrib (cdr L) E))
  )
)
```

127

```
We will let (extend L E) extend a
    list L by distributing element E
    through L and then appending
    this result to L.
    For example,
     (extend '( () (a) ) 'b) \Rightarrow
      (()(a)(b)(b a))
    (define (extend L E)
       (append L (distrib L E))
    Now subsets is easy:
    (define (subsets L)
       (if (null? L)
           (list ())
           (extend (subsets (cdr L))
                    (car L))
      )
    )
CS 538 Spring 2008
                                          129
```

### DATA STRUCTURES IN SCHEME In Scheme, lists and S-expressions are basic. Arrays can be simulated using lists, but access to elements "deep" in the list can be slow (since a list is a linked structure). To access an element deep within a list we can use: • (list-tail L k) This returns list **L** after removing the first $\mathbf{k}$ elements. For example, (list-tail '(1 2 3 4 5) 2) $\Rightarrow$ (3 4 5)• (list-ref L k) This returns the k-th element in L (counting from 0). For example, (list-ref ' $(1 \ 2 \ 3 \ 4 \ 5)$ 2) $\Rightarrow$ 3

CS 538 Spring 2008

130

# **VECTORS IN SCHEME**

Scheme provides a vector type that directly implements one dimensional arrays. Literals are of the form  $\#(\dots)$ For example, #(1 2 3) or #(1 2.0 "three") The function (vector? val) tests whether **val** is a vector or not. (vector? 'abc)  $\Rightarrow #f$ (vector?  $(a b c)) \Rightarrow #f$ (vector?  $\#(a b c)) \implies \#t$ The function (vector v1 v2 ...) evaluates v1, v2, ... and puts them into a vector. (vector 1 2 3)  $\Rightarrow$  #(1 2 3)

The function (make-vector k val) creates a vector composed of k copies of val. Thus (make-vector 4 (/ 1 2))  $\Rightarrow$  $\#(1/2 \ 1/2 \ 1/2 \ 1/2)$ The function (vector-ref vect k) returns the k-th element of vect, starting at position 0. It is essentially the same as **vect[k]** in C or Java. For example,  $(vector-ref \#(2 \ 4 \ 6 \ 8 \ 10) \ 3) \Rightarrow 8$ The function (vector-set! vect k val) SetS the **k**-th element of **vect**, starting at position 0, to be **val**. It is essentially the same as **vect[k]=val** in C or Java. The value returned by the function is unspecified. The suffix "!" in **set!** indicates that the function has a side-effect.

# **Records and Structs**

In Scheme we can represent a record, struct, or class object as an *association list* of the form ((obj1 val1) (obj2 val2) ...) In the association list, which is a list of (object value) sublists, object serves as a "key" to locate the desired sublist.

For example, the association list

( (A 10) (B 20) (C 30) )

serves the same role as

struct

{ int a = 10; int b = 20; int c = 30;}

# The predefined Scheme function (assoc obj alist)

checks **alist** (an association list) to see if it contains a sublist with **obj** as its head. If it does, the list starting with **obj** is returned; otherwise **#f** (indicating failure) is returned.

For example,

```
(define L

'( (a 10) (b 20) (c 30) ) )

(assoc 'a L) \Rightarrow (a 10)

(assoc 'b L) \Rightarrow (b 20)

(assoc 'x L) \Rightarrow #f
```

```
We can use non-atomic objects as
    kevs too!
    (define price-list
       '( ((bmw m5)
                            71095)
           ((bmw z4))
                            40495)
           ((jag xj8)
                            56975)
           ((mb s1500)
                            86655)
        )
    )
     (assoc '(bmw z4) price-list)
         \Rightarrow ((bmw z4)
                         40495)
CS 538 Spring 2008
                                           137
```

```
Using assoc, we can easily define
a structure function:
(structure key alist) Will
return the value associated with
key in alist; in C or Java
notation. it returns alist.key.
(define
  (structure key alist)
  (if (assoc key alist)
    (car (cdr (assoc key alist)))
    #f
  )
)
We can improve this function in
two ways:
• The same call to assoc is made
 twice; we can save the value
 computed by using a let
 expression.

    Often combinations of car and cdr

 are needed to extract a value.
```

```
Scheme has a number of
 predefined functions that combine
 several calls to car and cdr into
 one function. For example,
 (caar x) \equiv (car (car x))
 (cadr x) \equiv (car (cdr x))
 (cdar x) \equiv (cdr (car x))
 (cddr x) \equiv (cdr (cdr x))
 Using these two insights we can
 now define a better version of
 structure
(define
   (structure key alist)
   (let ((p (assoc key alist)))
     (if p
         (cadr p)
        #£
     )
   )
)
```

What does **assoc** do if more than one sublist with the same key exists?

It returns the first sublist with a matching key. In fact, this property can be used to make a simple and fast function that updates association lists:

(define (set-structure key alist val) (cons (list key val) alist) )

CS 538 Spring 2008

If we want to be more spaceefficient, we can create a version that updates the internal structure of an association list, using **set-cdr!** which changes the **cdr** value of a list: (define (set-structure! key alist val) (let ( (p (assoc key alist)))

```
(if p
  (begin
      (set-cdr! p (list val))
      alist
  )
  (cons (list key val) alist)
)
```

# Functions are First-class Objects

Functions may be passed as parameters, returned as the value of a function call, stored in data objects, etc.

This is a consequence of the fact that

(lambda (args) (body))
evaluates to a function just as
(+ 1 1)

evaluates to an integer.

CS 538 Spring 2008

) )

# 141

CS 538 Spring 2008

# Scoping

In Scheme scoping is static (lexical). This means that nonlocal identifiers are bound to containing lambda parameters, or let values, or globally defined values. For example,

(define (f x)

```
(lambda (y) (+ x y)))
```

Function  $\mathbf{f}$  takes one parameter, **x**. It returns a function (of **y**), with **x** in the returned function bound to the value of **x** used when  $\mathbf{f}$  was called.

### Thus

(f 10)  $\equiv$  (lambda (y) (+ 10 y)) ((f 10) 12)  $\Rightarrow$  22 Unbound symbols are assumed to be globals; there is a run-time error if an unbound global is referenced. For example,

(define (p y) (+ x y))

(p 20) ; error -- x is unbound (define x 10)

### $(p 20) \Rightarrow 30$

We can use let bindings to create private local variables for functions:

```
(define F
			(let ( (X 1) )
			(lambda () X)
		)
F is a function (of no arguments).
(F) Calls F.
(define X 22)
(F) ⇒ 1;X used in F is private
```
```
We can encapsulate internal state
     with a function by using private,
     let-bound variables:
     (define cnt
         (let ( (I 0) )
           (lambda ()
                (set! I (+ I 1)) I)
         )
     )
     Now.
        (cnt) \Rightarrow 1
        (cnt) \Rightarrow 2
        (cnt) \Rightarrow 3
       etc.
CS 538 Spring 2008
                                                145
```

#### LET BINDINGS CAN DE SUDTLE You must check to see if the letbound value is created when the function is *created* or when it is called. Compare (define cnt (let ( (I 0) ) (lambda () (set! I (+ I 1)) I) ) ) vs. (define reset (lambda () (let ( (I 0) ) (set! I (+ I 1)) I) ) ) (reset) $\Rightarrow$ 1, (reset) $\Rightarrow$ 1, etc.

CS 538 Spring 2008

146

# Simulating Class Objects

Using association lists and private bound values, we can *encapsulate* data and functions. This gives us the effect of class objects.

```
(define (point x y)
  (list
   (list 'rect
         (lambda () (list x y)))
   (list 'polar
         (lambda ()
          (list
           (sqrt (+ (* x x) (* y y)))
           (atan (/ x y))
          )
         )
  )
 )
)
A call (point 1 1) creates an
association list of the form
( (rect funct) (polar funct) )
```

We can use structure to access components: (define p (point 1 1) ) ( (structure 'rect p) )  $\Rightarrow$  (1 1) ( (structure 'polar p) )  $\Rightarrow$  $(\sqrt{2} \frac{\pi}{4})$ 

```
We can add new functionality by
     just adding new (id function)
     pairs to the association list.
     (define (point x y)
       (list
        (list 'rect
              (lambda () (list x y)))
        (list 'polar
              (lambda ()
               (list
                 (sqrt (+ (* x x) (* y y)))
                 (atan (/ x y))
        )))
        (list 'set-rect!
               (lambda (newx newy)
                       (set! x newx)
                       (set! y newy)
                       (list x y)
        ))
        (list 'set-polar!
               (lambda (r theta)
                 (set! x (* r (sin theta)))
                 (set! y (* r (cos theta)))
                 (list r theta)
        ))
     ))
CS 538 Spring 2008
                                              149
```

```
Now we have

(define p (point 1 1)) ((structure 'rect p)) \Rightarrow (1 1) ((structure 'polar p)) \Rightarrow (\sqrt{2} \frac{\pi}{4})
((structure 'set-polar! p) 1 \pi/4) \Rightarrow (1 \pi/4) ((structure 'rect p)) \Rightarrow (\frac{1}{\sqrt{2}} \frac{1}{\sqrt{2}})
```

#### Limiting Access to Internal Structure

We can improve upon our association list approach by returning a single function (similar to a C++ or Java object) rather than an explicit list of (id function) pairs.

The function will take the name of the desired operation as one of its arguments.

```
First, let's differentiate between
(define def1
  (let ( (I 0) )
      (lambda () (set! I (+ I 1)) I)
  )
and
(define (def2)
  (let ( (I 0) )
      (lambda () (set! I (+ I 1)) I)
  )
def1 is a zero argument function
that increments a local variable
and returns its updated value.
```

**def2** is a a zero argument function that *generates* a function of zero arguments (that increments a local variable and returns its updated value). Each call to **def2** creates a *different* function.

# STACK IMPLEMENTED AS A FUNCTION

```
(define ( stack )
       (let ( (s () ) )
         (lambda (op . args) ; var # args
          (cond
           ((equal? op 'push!)
             (set! s (cons (car args) s))
             (car s))
           ((equal? op 'pop!)
              (if (null? s)
                 #f
                  (let ( (top (car s)) )
                      (set! s (cdr s))
                      top )))
           ((equal? op 'empty?)
            (null? s))
           (else
                   #£)
           )
          )
       )
     )
CS 538 Spring 2008
                                             153
```

```
(define stk (stack)); new empty stack
(stk 'push! 1) <math>\Rightarrow 1 ; s = (1)
(stk 'push! 3) \Rightarrow 3 ; s = (3 1)
(stk 'push! 'x) \Rightarrow x ; s = (x 3 1)
(stk 'pop!) \Rightarrow x ; s = (3 1)
(stk 'empty?) \Rightarrow #f ; s = (3 1)
(stk 'dump) \Rightarrow #f ; s = (3 1)
```

# **Higher-Order Functions**

A higher-order function is a function that takes a function as a parameter or one that returns a function as its result.

A very important (and useful) higher-order function is map, which applies a function to a list of values and produces a list or results:

```
of function application is unspecified.
```

 $(map \ sqrt \ (1 \ 2 \ 3 \ 4 \ 5)) \Rightarrow$ (1 1.414 1.732 2 2.236) (map (lambda(x) (\* x x)) (1 2 3 4 5))  $\Rightarrow$ (1 4 9 16 25) Map may also be used with multiple argument functions by supplying more than one list of arguments: (map + '(1 2 3) '(4 5 6))  $\Rightarrow$ (5 7 9)

The Reduce Function
Another useful higher-order function is reduce, which reduces a list of values to a single value by repeatedly applying a binary function to the list values. This function takes a binary function, a list of data values, and an identity value for the binary function: (define (reduce f L id) (if (null? L) id (f (car L) (reduce f (cdr L) id)) ) ) (reduce + '(1 2 3 4 5) 0) $\Rightarrow$ 15 (reduce * '(1 2 4 6 8 10) 1) $\Rightarrow$ 3840
C5 538 Spring 2008 157

But, if side-effects are possible we
may need to force a physical copy
of an object or structure:
(define (copy obj)
 (if (pair? obj)
 (cons (copy (car obj)))
 (copy (cdr obj)))
 obj
 )
)

CS 538 Spring 2008

# Shallow & DEEP Copying

A copy operation that copies a pointer (or reference) rather than the object itself is a *shallow copy*. For example, In Java,

Object O1 = new Object();

Object O2 = new Object();

01 = 02; // shallow copy

If the structure within an object is physically copied, the operation is a *deep copy*.

In Java, for objects that support the clone operation,

01 = 02.clone(); // deep copy

Even in Java's deep copy (via the **clone()** operation), objects referenced from within an object are shallow copied. Thus given

```
class List {
  int value;
  List next;
}
List L,M;
M = L.clone();
L.value and M.value are
independent, but L.next and
M.next refer to the same List
obiect.
A complete deep copy, that copies
all objects linked directly or
indirectly, is expensive and tricky
to implement.
(Consider a complete copy of a
circular linked list).
```

# EQUALITY CHECKING IN SCHEME

In Scheme = is used to test for numeric equality (including comparison of different numeric types). Non-numeric arguments cause a run-time error. Thus

 $(= 1 1) \Rightarrow \#t$  $(= 1 1.0) \Rightarrow \#t$  $(= 1 2/2) \Rightarrow \#t$  $(= 1 1+0.0i) \Rightarrow \#t$ 

CS 538 Spring 2008

165

CS 538 Spring 2008

To compare non-numeric values, we can use either:

*pointer equivalence* (do the two operands point to the same address in memory)

structural equivalence (do the two operands point to structures with the same size, shape and components, even if they are in different memory locations)

In general pointer equivalence is faster but less accurate.

Scheme implements both kinds of equivalence tests.

(eqv? obj1 obj2)

This tests if **obj1** and **obj2** are the exact same object. This works for atoms and pointers to the same structure.

```
(equal? obj1 obj2)
This tests if obj1 and obj2 are
the same, component by
component. This works for
atoms, lists, vectors and strings.
(eqv? 1 1) \Rightarrow #t
(eqv? 1 (+ 0 1)) \Rightarrow #t
(eqv? 1/2 (-1 1/2)) \implies #t
(eqv? (cons 1 2) (cons 1 2)) \Rightarrow
   #f
(eqv? "abc" "abc") \Rightarrow #f
(equal? 1 1) \Rightarrow #t
(equal? 1 (+ 0 1)) \Rightarrow #t
(equal? 1/2 (- 1 1/2)) \Rightarrow #t
(equal? (cons 1 2) (cons 1 2)) \Rightarrow
  #t
(equal? "abc" "abc") \Rightarrow #t
```

In general it is wise to use **equal?** unless speed is a critical factor.

# I/O in Scheme

Scheme has simple read and write functions, directed to the "standard in" and "standard out" files.

#### (read)

Reads a single Scheme object (an atom, string, vector or list) from the standard in file. No quoting is needed.

#### (write obj)

Writes a single object, **obj**, to the standard out file.

#### (display obj)

Writes **obj** to the standard out file in a more readable format. (Strings aren't quoted, and characters aren't escaped.)

#### (newline)

Forces a new line on standard out file.

CS 538 Spring 2008

#### 169

# Ports

Ports are Scheme objects that interface with systems files. I/O to files is normally done through a port object bound to a system file.

(open-input-file "path to file") This returns an input port associated with the "path to file" string (which is system dependent). A run-time error is signalled if "path to file" specifies an illegal or inaccessible file.

#### (read port)

Reads a single Scheme object (an atom, string, vector or list) from **port**, which must be an input port object.

CS 538 Spring 2008

(eof-object? obj)

When the end of an input file is reached, a special eof-object is returned. **eof-object?** tests whether an object is this special end-of-file marker.

(open-output-file "path to file") This returns an output port associated with the "path to file" string (which is system dependent). A run-time error is signalled if "path to file" specifies an illegal or inaccessible file.

#### (write obj port)

Writes a single object, **obj**, to the output port specified by **port**.

#### (display obj port)

Writes **obj** to the output port specified by **port**. display uses a more readable format than write does. (Strings aren't quoted, and characters aren't escaped.)

#### (close-input-port port)

This closes the input port specified by **port**.

(close-output-port port) This closes the output port specified by port.

171

# Example—Reading & Echoing a File

We will iterate through a file, reading and echoing its contents. We need a good way to do iteration; recursion is neither natural nor efficient here.

Scheme provides a nice generalization of the **let** expression that is similar to C's for loop.

(let X ( (id1 val1) (id2 val2) ... ) ...

(X v1 v2 ...)

A name for the let (**x** in the example) is provided. As usual, **val1** is evaluated and bound to **id1**, **val2** is evaluated and bound to **id2**, etc. In the body of the let, the let may be "called" (using its

CS 538 Spring 2008

)

name) with a fresh set of values for the let variables. Thus (x v1 v2 ...) starts the next iteration of the let with id1 bound to v1. id2, bound to v2, etc. The calls look like recursion, but they are implemented as loop iterations. For example, in (let loop ( (x 1) (sum 0) ) (if (<= x 10)(100p (+ x 1) (+ sum x))sum ) ) we sum the values of  $\mathbf{x}$  from 1 to 10. Compare it to for (x=1, sum=0; x <= 10;sum + = x, x + = 1) {}

CS 538 Spring 2008

173

Now a function to read and echo a file is straightforward: (define (echo filename) (let ( (p (open-input-file filename))) (let loop ( (obj (read p))) (if (eof-object? obj) #t ;normal termination (begin (write obj) (newline) (loop (read p)) ) ) ) ) )

```
We can create an alternative to
echo that uses
(call-with-input-file
   filename function)
This function opens filename,
creates an input port from it, and
then calls function with that
port as an argument:
(define (echo2 filename)
  (call-with-input-file filename
    (lambda(port)
      (let loop ( (obj (read port)))
         (if (eof-object? obj)
         #t
          (begin
            (write obj)
            (newline)
            (loop (read port))
         )
         )
       )
    )
))
```

CS 538 Spring 2008

```
As an example, consider a simple
function that multiplies a list of
integers:
(define (*list L)
  (if (null? L)
      1
      (* (car L)(*list (cdr L)))
  )
)
The call (*1ist '(1 2 3 4 5))
expands to
(* 1 (* 2 (* 3 (* 4 (* 5 1)))))
But,
what if we get clever and decide
to improve this function by noting
that if 0 appears anywhere in list
L, the product must be 0?
```

CS 538 Spring 2008

Let's try (define (\*list0 L) (cond ((null? L) 1) ((= 0 (car L)) 0)(else (\* (car L) (\*list0 (cdr L)))) ) ) This helps a bit—we never go past a zero in **L**, but we still unnecessarily do a sequence of pending multiplies, all of which must vield zero! Can we escape from a sequence of nested calls once we know they're unnecessary?

#### **Exceptions**

In languages like Java, a statement may *throw* an exception that's *caught* by an enclosing exception handler. Code between the statement that throws the exception and the handler that catches it is *abandoned*.

Let's solve the problem of avoiding multiplication of zero in Java, using its exception mechanism:

```
class Node {
```

int val;

Node next;

class Zero extends Throwable
 {};

}

```
int mult (Node L) {
  try {
    return multNode(L);
  } catch (Zero z) {
    return 0;
  }
}
int multNode(Node L)
   throws Zero {
  if (L == null)
    return 1;
  else if (L.val == 0)
    throw new Zero();
  else return
   L.val * multNode(L.next);
}
In this implementation, no
multiplies by zero are ever done.
```

```
Continuations
```

In our Scheme implementation of **\*list**, we'd like a way to delay doing any multiplies until we know no zeros appear in the list. One approach is to build a *continuation*—a function that represents the context in which a function's return value will be used:

```
(define (*listC L con)
  (cond
      ((null? L) (con 1))
      ((= 0 (car L)) 0)
      (else
      (*listC (cdr L)
            (lambda (n)
                        (* n (con (car L)))))
  )
  )
)
)
```

```
CS 538 Spring 2008
```

182

The top-level call is (\*listC L (lambda (x) x)) For ordinary lists **\*listC** expands to a series of multiplies, just like \*list did. (define (id x) x) (\*listC '(1 2 3) id)  $\Rightarrow$ (\*listC '(2 3)  $(lambda (n) (* n (id 1))) \equiv$ (\*listC '(2 3) (lambda (n) (\* n 1)))  $\Rightarrow$ (\*listC '(3)  $(lambda (n) (* n (* 2 1))) \equiv$ (\*listC '(3) (lambda (n) (\* n 2)))  $\Rightarrow$ (\*listC ()  $(lambda (n) (* n (* 3 2)))) \equiv$ (\*listC () (lambda (n) (\* n 6)))  $\Rightarrow$  (\* 1 6)  $\Rightarrow$  6

But for a list with a zero in it, we
get a different execution path:
(\*listC '(1 0 3) id) ⇒
(\*listC '(0 3)
 (lambda (n) (\* n (id 1)))) ⇒ 0
No multiplies are done!

181

CS 538 Spring 2008

CS 538 Spring 2008

# Another Example of Continuations

Let's redo our list multiply example so that if a zero is seen in the list we return a function that computes the product of all the non-zero values and a parameter that is the "replacement value" for the unwanted zero value. The function gives the caller a chance to correct a probable error in the input data.

We create

(\*list2 L)  $\equiv$ 

Product of all integers in L if no zero appears else (lambda (n) (\* n product-of-allnonzeros-in-L)

CS 538 Spring 2008

185

CS 538 Spring 2008

For ordinary lists **\*list2** expands to a series of multiplies, just like **\*list** did.

```
(*listE '(1 2 3) id) \Rightarrow
(*listE '(2 3) (lambda (m) (* m (id 1)))) \equiv
(*listE '(2 3) (lambda (m) (* m 1))) \Rightarrow
(*listE '(3) (lambda (m) (* m (* 2 1)))) \equiv
(*listE '(3) (lambda (m) (* m 2))) \Rightarrow
(*listE () (lambda (m) (* m (* 3 2)))) \equiv
(*listE () (lambda (n) (* n 6))) \Rightarrow
```

```
But for a list with a zero in it, we
get a different execution path:
(*listE '(1 0 3) id) \Rightarrow
(*listE '(0 3)
  (lambda (m) (* m (id 1))) \Rightarrow
(lambda (n) (* (con n)
   (* listE '(3) id)))
                           \equiv
(lambda (n) (* (* n 1)
   (* listE '(3) id)))
                            \equiv
(lambda (n) (* (* n 1) 3))
This function multiplies \mathbf{n}, the
replacement value for 0, by 1 and
3, the non-zero values in the input
list.
```

```
But note that only one zero value
     in the list is handled correctly!
    Whv?
     (define (*listE L con)
       (cond
         ((null? L) (con 1))
         ((= 0 (car L))
            (lambda(n)
             (* (con n)
                (*listE (cdr L) id))))
         (else
          (*listE (cdr L)
            (lambda(m)
             (* m (con (car L))))))

CS 538 Spring 2008

## **CONTINUATIONS IN SCHEME**

Scheme provides a built-in mechanism for creating continuations. It has a long name:

**call-with-current-continuation** This name is often abbreviated as

call/cc

(perhaps using define).

**call/cc** takes a single function as its argument. That function also takes a single argument. That is, we use **call/cc** as

(call/cc funct) where

funct = (lambda (con) (body))
call/cc calls the function that it
is given with the "current
continuation" as the function's
argument.

## **CURRENT CONTINUATIONS**

What is the current continuation? It is itself a function of one argument. The current continuation function represents the execution context within which the call/cc appears. The argument to the continuation is a value to be substituted as the return value of call/cc in that execution context.

For example, given

(+ (fct n) 3)

the current continuation for (fct n) is (lambda (x) (+ x 3))

Given (\* 2 (+ (fct z) 10))

the current continuation for (fct z) is (lambda (m) (\* 2 (+ m 10))

#### Continuations are Just Functions

Continuations may be saved in variables or data structures and called in the future to "reactive" a completed or suspended computation. (define CC ()) (define (F) (let ( (v (call/cc (lambda(here) (set! CC here) 1)))) (display "The ans is: ") (display v) (newline) )) This displays The ans is: 1 At any time in the future, (cc 10) will display The ans is: 10

# LIST MULTIPLICATION REVISITED

```
We can use call/cc to
reimplement the original *list to
force an immediate return of 0
(much like a throw in Java):
(define (*listc L return)
  (cond
    ((null? L) 1)
    ((= 0 (car L)) (return 0))
    (else (* (car L)
        (*listc (cdr L) return)))
))
(define (*list L)
  (call/cc
   (lambda (return)
     (*listc L return)
) ))
A o in L forces a call of (return
o) which makes o the value of
```

195

call/cc.

# INTERACTIVE REPLACEMENT OF ERROR VALUES

Using continuations, we can also redo **\*listE** so that zeroes can be replaced interactively! Multiple zeroes (in both original and replacement values) are correctly handled.

(define (*list L)
(let (
(V (call/cc
(lambda (here)
(*liste L here))))))
(if (number? V)
v
(begin
(display
"Enter new value for 0")
(newline) (newline)
(V (read))
)
)
, )
) ´
,

CS 538 Spring 2008

continuation that will set the next value of **value**. This value is checked, so if it is itself zero, a substitute is requested. Each occurrence of zero forces a return to the caller for a substitute value.

CS 538 Spring 2008

197

# Implementing Coroutines with call/cc

Coroutines are a very handy generalization of subroutines. A coroutine may *suspend* its execution and later *resume* from the point of suspension. Unlike subroutines, coroutines do no have to complete their execution before they return.

Coroutines are useful for computation of long or infinite streams of data, where we wish to compute some data, use it, compute additional data, use it, etc.

Subroutines aren't always able to handle this, as we may need to save a lot of internal state to resume with the correct next value.

## Producer/Consumer using Coroutines

The example we will use is one of a consumer of a potentially infinite stream of data. The next integer in the stream (represented as an unbounded list) is read. Call this value n. Then the next n integers are read and summed together. The answer is printed, and the user is asked whether another sum is required. Since we don't know in advance how many integers will be needed, we'll use a coroutine to produce the data list in segments, requesting another segment as necessary.

199

CS 538 Spring 2008

202

The function moredata is called whenever we need more data. Initially a producer function is called to get the initial segment of data. producer actually returns the next data segment *plus* a continuation (stored in producer-cc) used to resume execution of producer when the next data segment is required.

The function **producer** generates an infinite sequence of integers (1,2,3,...). It suspends every 5/ 10/15/25 elements and returns control to moredata. (define (producer initial-return) (let loop ( (return initial-return) ) (set! return (call/cc (lambda (here) (return (cons (next 5) here))))) (set! return (call/cc (lambda (here) (return (cons (next 10) here))))) (set! return (call/cc (lambda (here) (return (cons (next 15) here))))) (loop (call/cc (lambda (here) (return (cons (next 25) here))))) ) ) CS 538 Spring 2008

CS 538 Spring 2008

## **Reading Assignment**

 MULTILISP: a language for concurrent symbolic computation, by Robert H. Halstead (linked from class web page)

#### LAZY EVALUATION

Lazy evaluation is sometimes called "call by need." We do an evaluation when a value is used; not when it is defined.

Scheme provides for lazy evaluation:

#### (delay expression)

Evaluation of **expression** is delayed. The call returns a "promise" that is essentially a lambda expression.

#### (force promise)

A promise, created by a call to **delay**, is evaluated. If the promise has already been evaluated, the value computed by the first call to **force** is reused.

207

205

```
An argument to a function is strict
if it is always used. Non-strict
arguments may cause failure if
evaluated unnecessarily.
With lazy evaluation, we can
define a more robust and
function:
(define (and A B)
  (if A
     (force B)
     #f
  )
)
This is called as:
(and (not (= i 0))
     (delay (> (/ j i) 10)))
Note that making the programmer
remember to add a call to delay
is unappealing.
```

CS 538 Spring 2008

209

Delayed evaluation also allows us a neat implementation of suspensions. The following definition of an infinite list of integers clearly fails: (define (inflist i) (cons i (inflist (+ i 1)))) But with use of delays we get the desired effect in finite time: (define (inflist i) (cons i (delay (inflist (+ i 1))))) Now a call like (inflist 1) creates promise for (inflist 2)

We need to slightly modify how we explore suspended infinite lists. We can't redefine **car** and **cdr** as these are far too fundamental to tamper with. Instead we'll define **head** and

tail to do much the same job:

(define head car)

(define (tail L)

(force (cdr L)))

**head** looks at **car** values which are fully evaluated.

**tail** forces one level of evaluation of a delayed **cdr** and saves the evaluated value in place of the suspension (promise).

211

CS 538 Spring 2008

#### **Exploiting Parallelism**

Conventional procedural programming languages are difficult to compile for multiprocessors.

Frequent assignments make it difficult to find independent computations.

Consider (in Fortran): do 10 I = 1,1000 X(I) = 0 A(I) = A(I+1)+1 B(I) = B(I-1)-1 C(I) = (C(I-2) + C(I+2))/2 10 continue

This loop defines 1000 values for arrays **x**, **a**, **b** and **c**.

CS 538 Spring 2008

Which computations can be done in parallel, partitioning parts of an array to several processors, each operating independently?

- x(I) = 0 Assignments to x can be readily parallelized.
- A(I) = A(I+1)+1

Each update of **A**(**I**) uses an **A**(**I**+1) value that is not yet changed. Thus a whole array of new **A** values can be computed from an array of "old" **A** values in parallel.

B(I) = B(I-1)-1 This is less obvious. Each B(I) uses B(I-1) which is defined in terms of B(I-2), etc. Ultimately all new B values depend only on B(0) and I. That is, B(I) = B(0) - I. So this computation can be parallelized, but it takes a fair amount of insight to realize it.  C(I) = (C(I-2) + C(I+2))/2 It is clear that even and odd elements of c don't interact. Hence two processors could compute even and odd elements of c in parallel. Beyond this, since both earlier and later c values are used in each computation of an element, no further means of parallel evaluation is evident. Serial evaluation will probably be needed for even or odd values.

CS 538 Spring 2008

## CONCURRENTIZATION

Concurrentization (often called parallelization) is process of automatically finding potential concurrent execution in a serial program.

Automatically finding current execution is complicated by a number of factors:

Data Dependence

Not all expressions are independent. We may need to delay evaluation of an operator or subprogram until its operands are available.

Thus in

(+ (\* x y) (\* y z))

we can't start the addition until both multiplications are done.

 Control Dependence Not all expressions need be (or should be evaluated. In (if (= a 0))0 (/ b a)) we don't want to do the division until we know  $a \neq 0$ . Side Effects If one expression can write a value that another expression might read, we probably will need to serialize their execution. Consider (define rand! (let ((seed 99)) (lambda () (set! seed (mod (\* seed 1001) 101101)) seed ))))

219

#### Now in

# (+ (f (rand!)) (g (rand!))) we can't evaluate (f (rand!)) and (g (rand!)) in parallel, because of the side effect of set! in rand!. In fact if we did, f and g might see exactly the same "random" number! (Why?)

#### Granularity

Evaluating an expression concurrently has an overhead (to setup a concurrent computation). Evaluating very simple expressions (like (car x) or (+ x 1)) in parallel isn't worth the overhead cost.

Estimating where the "break even" threshold is may be tricky.

# Utility of Concurrentization

Concurrentization has been most successful in engineering and scientific programs that are very regular in structure, evaluating large multidimensional arrays in simple nested loops. Many very complex simulations (weather, fluid dynamics, astrophysics) are run on multiprocessors after extensive concurrentization.

Concurrentization has been far less successful on non-scientific programs that don't use large arrays manipulated in nested for loops. A compiler, for example, is difficult to run (in parallel) on a multiprocessor.

CS 538 Spring 2008

221

# Concurrentization within **Processors**

Concurrentization is used extensively within many modern uniprocessors. Pentium and PowerPC processors routinely execute several instructions in parallel if they are independent (e.g., read and write distinct registers). This are *superscalar* processors.

These processors also routinely *speculate* on execution paths, "guessing" that a branch will (or won't) be taken even before the branch is executed! This allows for more concurrent execution than if strictly "in order" execution is done. These processors are called "out of order" processors.

## Adding Parallel Features to Programming Languages.

It is common to take an existing serial programming language and add features that support concurrent or parallel execution. For example versions for Fortran (like HPF—High Performance Fortran) add a parallel do loop that executes individual iterations in parallel.

Java supports threads, which may be executed in parallel. Synchronization and mutual exclusion are provided to avoid unintended interactions.

CS 538 Spring 2008

# Multilisp

Multilisp is a version of Scheme augmented with three parallel evaluation mechanisms:

- Pcall Arguments to a call are evaluated in parallel.
- Future Evaluation of an expression starts immediately. Rather than waiting for completion of the computation, a "future" is returned. This future

will eventually transform itself into the result value (when the computation completes)

• Delay

Evaluation is delayed until the result value is really needed.

#### CS 538 Spring 2008

225

# THE PCALL MECHANISM

Pcall is an extension to Scheme's function call mechanism that causes the function and its arguments to be all computed in parallel. Thus

#### (pcall F X Y Z)

causes  $\mathbf{F}$ ,  $\mathbf{x}$ ,  $\mathbf{y}$  and  $\mathbf{z}$  to all be evaluated in parallel. When all evaluations are done,  $\mathbf{F}$  is called with  $\mathbf{x}$ ,  $\mathbf{y}$  and  $\mathbf{z}$  as its parameters (just as in ordinary Scheme).

Compare

(+ (\* X Y) (\* Y Z)) with (pcall + (\* X Y) (\* Y Z))

CS 538 Spring 2008

It may not look like **pcall** can give you that much parallel execution, but in the context of recursive definitions, the effect can be dramatic.

Consider treemap, a version of map that operates on binary trees (S-expressions).

```
(define (treemap fct tree)
 (if (pair? tree)
  (pcall cons
      (treemap fct (car tree))
      (treemap fct (cdr tree))
  )
  (fct tree)
))
```

Look at the execution of treemap on the tree  $(((1 \cdot 2) \cdot (3 \cdot 4)) \cdot ((5 \cdot 6) \cdot (7 \cdot 8)))$ We start with one call that uses the whole tree. This splits into two parallel calls, one operating on  $((1 \cdot 2) \cdot (3 \cdot 4))$ and the other operating on  $((5 \cdot 6) \cdot (7 \cdot 8))$ Each of these calls splits into 2 calls, and finally we have 8 independent calls, each operating on the values 1 to 8.

#### FUTURES

Evaluation of an expression as a future is the most interesting feature of Multilisp.

The call

#### (future expr)

begins the evaluation of **expr**. But rather than waiting for **expr**'s evaluation to complete, the call to **future** returns *immediately* with a new kind of data object—a future. This future is actually an "IOU." When you try to use the value of the future, the computation of **expr** may or may not be completed. If it is, you see the value computed instead of the future—it automatically transforms itself. Thus evaluation of **expr** appears instantaneous. If the computation of **expr** is not yet completed, you are forced to wait until computation is completed. Then you may use the value and resume execution.

But this is exactly what ordinary evaluation does anyway—you begin evaluation of expr and wait until evaluation completes and returns a value to you!

To see the usefulness of futures, consider the usual definition of Scheme's map function:

CS 538 Spring 2008

229

CS 538 Spring 2008

If we have a call (map slow-function long-list) where slow-function executes slowly and long-list is a large data structure, we can expect to wait quite a while for computation of the result list to complete.

Now consider fastmap, a version
of map that uses futures:
(define (fastmap f L)
 ()
 (cons
 (future (f (car L)))
 (fastmap f (cdr L))
 )
 )
)

Now look at the call (fastmap slow-function long-list)

We will exploit a useful aspect of futures—they can be cons'ed together *without delay*, even if the computation isn't completed yet.

Why? Well a **cons** just stores a pair of pointers, and it really doesn't matter what the pointers reference (a future or an actual result value).

The call to **fastmap** can actually return before *any* of the call to **slow-function** have completed:

#### ANOTHER EXAMPLE OF FUTURES

The following function, **partition**, will take a list and a data value (called **pivot**). **partition** will partition the list into two sublists:

```
(a) Those elements \leq pivot
```

We want to add futures to partition, but where?

It makes sense to use a future when a computation may be lengthy and we may not need to use the value computed immediately.

What computation fits that pattern?

The computation of tail-part. We'll mark it in a blue box to show we plan to evaluate it using a future:

```
(define (partition pivot L)
      (if (null? L)
        (cons () () )
        (let ((tail-part
              (partition pivot (cdr L))))
          (if (<= (car L) pivot)
           (cons
            (cons (car L) (car tail-part))
             (cdr tail-part))
           (cons
            (car tail-part))
            (cons (car L) (cdr tail-part))
          )
     ))))
     But this one change isn't enough!
     We soon access the car and cdr
     of tail-part, which forces us to
     wait for its computation to
     complete. To avoid this delay, we
     can place the four references to
     car or cdr of tail-part into
     futures too:
CS 538 Spring 2008
                                           237
```

Now we can build the initial part of the partitioned list (that involving **pivot** and (**car L**) *independently* of the recursive call of **partition**, which completes the rest of the list.

For example,

(partition 17 '(5 3 8 ...))
creates a future (call it future1)
to compute

(partition 17 '(3 8 ...))

It also creates future2 to compute (car tail-part) and future3 to compute (cdr tailpart). The call builds

# **Reading Assignment**

 Introduction to Standard ML (linked from class web page)

• Webber: Chapters 5, 7, 9, 11

CS 538 Spring 2008

CS 538 Spring 2008

#### 4. Pattern-directed Programming ML-META LANGUAGE fun len([]) = 0SML is *Standard ML*, a popular ML len(a::b) = 1+len(b);variant. 5. Exceptions ML is a functional language that is 6. First-class functions designed to be efficient and type-7. Abstract Data Types safe. It demonstrates that a functional language need not use coin of int | Scheme's odd syntax and need bill of int not bear the overhead of dynamic check of string\*real; val dime = coin(10); typing. SML's features and innovations A good ML reference is include: "Elements of ML Programming," 1. Strong, compile-time typing. by leffrey Ullman 2. Automatic *type inference* (Prentice Hall, 1998) rather than user-supplied type declarations. 3. Polymorphism, including "type variables.'

CS 538 Spring 2008

241

#### **SML** is Interactive

You enter a definition or expression, and SML returns a result *with* an inferred type.

The command

use "file name";

loads a set of ML definitions from a file.

For example (SML responses are in blue):

```
21;
```

```
val it = 21 : int
```

```
(2 div 3);
```

```
val it = 0 : int
```

```
true;
```

```
val it = true : bool
```

```
"xyz";
val it = "xyz" : string
```

# **BASIC SML PREDEFINED TYPES**

#### • Unit

CS 538 Spring 2008

Its only value is (). Type **unit** is similar to **void** in C; it is used where a type is needed, but no "real" type is appropriate. For example, a call to a write function may return **unit** as its result.

Integer

Constants are sequences of digits. Negative values are prefixed with a ~ rather than a - (- is a binary subtraction operator). For example, ~123 is negative 123. Standard operators include

- + \* div mod
- < > <= >= = <>

```
    Real

  Both fractional (123.456) and
  exponent forms (10e7) are
  allowed. Negative signs and
  exponents use ~ rather than -
  (~10.0e~12).
  Standard operators include
          *
      -
  +
          <=
   <
               >=
  Note that = and <> aren't allowed!
  (Whv?)
  Conversion routines include
  real(int) to convert an int to a
  real.
  floor(real) to take the floor of
  a real.
  ceil(real) to take the ceiling of
  a real.
  round(real) to round a real,
  trunc(real) to truncate a real.
```

For example, real(3) returns 3.0, floor(3.1) returns 3, ceiling(3.3) returns 4, round(~3.6) returns ~4, trunc(3.9) returns 3. Mixed mode expressions, like 1 + 2.5 aren't allowed; you must do explicit conversion, like real(1) + 2.5

Strings

Strings are delimited by double quotes. Newlines are \n, tabs are \t, and \" and \\ escape double quotes and backslashes. E.g. "Bye now\n" The ^ operator is concatenation. "abc" ^ "def" = "abcdef"

The usual relational operators are provided: < > <= >= = <>

CS 538 Spring 2008

245

Characters

Single characters are delimited by double quotes and prefixed by a #. For example, **#"a"** or **#"\t"**. A character *is not* a string of length one. The **str** function may be used to convert a character into a string. Thus **str(#"a")** = **"a"** 

• Boolean

Constants are **true** and **false**. Operators include **andalso** (shortcircuit and), **orelse** (short-circuit or), **not**, = and <>.

A conditional expression,

(if boolval  $v_1$  else  $v_2$ ) is available.

# Tuples

CS 538 Spring 2008

A tuple type, composed of two or more values of any type is available.

Tuples are delimited by parentheses, and values are separated by commas.

Examples include:

```
(1,2);
val it = (1,2) : int * int
("xyz",1=2);
val it = ("xyz",false) :
string * bool
(1,3.0,false);
val it = (1,3.0,false) :
int * real * bool
(1,2,(3,4));
val it = (1,2,(3,4)) :
int * int * (int * int)
```

Equality is checked componentwise: (1,2) = (0+1,1+1);val it = true : bool (1,2,3) = (1,2) causes a compile-time type error (tuples must be of the same length and have corresponding types to be compared). **#i** selects the **i**-th component of a tuple (counting from 1). Hence #2(1,2,3);val it = 2 : int

CS 538 Spring 2008

249

#### Cons

Cons is an infix operator represented as ::

The left operand of **::** is any value of type **T**.

The right operand of **::** is any list of type **T** list.

The result of **::** is a list of type Tlist.

Hence **::** is *polymorphic*.

[] is the empty list. It has a type

'a list. The symbol 'a, read as "alpha" or "tic a" is a type variable. Thus [] is a *polymorphic* constant.

#### Lists

Lists are required to have a single element type for all their elements; their length is unbounded.

Lists are delimited by [ and ] and elements are separated by commas.

Thus [1,2,3] is an integer list. The empty (or null) list is [] or nil.

The cons operator is ::

Hence  $[1, 2, 3] \equiv 1::2::3::[]$ Lists are automatically typed by ML:

[1,2];val it = [1,2] : int list

CS 538 Spring 2008

250

# List Equality

Two lists may be compared for equality if they are of the same type. Lists **L1** and **L2** are considered equal if:

- (1) They have the same number of elements
- (2) Corresponding members of the two lists are equal.

## **List Operators**

 $\mathbf{hd} \equiv \mathbf{head} \text{ of list operator} \approx \mathbf{car}$ 

 $t1 \equiv tail of list operator \approx cdr$ 

**null** = null list predicate  $\approx$  **null**?

 $\mathbf{e} \equiv \text{infix list append operator} \approx$ append

# Records

Their general form is
{name1=val1, name2=val2, ... }
Field selector names are local to a
record.
For example:
 {a=1,b=2};
val it = {a=1,b=2} :
 {a:int, b:int}
 {a=1,b="xyz"};
val it = {a=1,b="xyz"} :
 {a:int, b:string}
 {a=1.0,b={c=[1,2]}} :
val it = {a=1.0,b={c=[1,2]}} :
}

The order of fields is irrelevant; equality is tested using field names.

```
{a=1,b=2}={b=2,a=2-1};
```

val it = true : bool

**#id** extracts the field named id from a record.

#b {a=1,b=2} ;
val it = 2 : int

CS 538 Spring 2008

253

# Identifiers

#### There are two forms:

Alphanumeric (excluding reserved words)

Any sequence of letters, digits, single quotes and underscores; must begin with a letter or single quote.

Case *is* significant. Identifiers that begin with a single quote are *type variables*.

Examples include:

abc a10 'polar sum\_of\_20

Symbolic

Any sequence (except predefined operators) of ! % & + - / : < = > ? @ \ ~ ^ | # Usually used for user-defined operators.

Examples include: ++ <=> !=

#### COMMENTS

CS 538 Spring 2008

Of form (\* text \*) May cross line boundaries.

# **Declaration of Values**

The basic form is

val id = expression;

This defines **id** to be bound to **expression**; ML answers with the name and value defined and the inferred type.

For example

val x = 10\*10;

val x = 100 : int

```
Redefinition of an identifier is OK,
     but this is redefinition not
     assignment;
    Thus
    val x = 100;
    val x = (x=100);
     is fine; there is no type error even
    though the first \mathbf{x} is an integer
     and then it is a boolean.
     val x = 100 : int
     val x = true : bool
CS 538 Spring 2008
                                             257
```

```
Examples
  val x = 1;
  val x = 1 : int
  val z = (x, x, x);
  val z = (1, 1, 1) : int * int * int
  val L = [z,z];
  val L = [(1,1,1), (1,1,1)]:
     (int * int * int) list
  val r = \{a=L\};
  val r = \{a=[(1,1,1),(1,1,1)]\}:
   {a:(int * int * int) list}
   After rebinding, the "nearest"
  (most recent) binding is used.
  The and symbol (not boolean and)
  is used for simultaneous binding:
  val x = 10;
  val x = 10 : int
  val x = true and y = x;
  val x = true : bool
  val y = 10 : int
```

*Local* definitions are temporary value definitions: local val x = 10in val u = x x;end; val u = 100 : int Let bindings are used in expressions: let val x = 10

```
in
   5*x
end;
val it = 50 : int
```

#### PATTERNS

CS 538 Spring 2008

Scheme (and most other languages) use *access* or *decomposition* functions to access the components of a structured object.

Thus we might write

(let ((h (car L) (t (cdr L)))) bodv )

Here **car** and **cdr** are used as access functions to locate the parts of **L** we want to access.

In ML we can access components of lists (or tuples, or records) *directly* by using patterns. The context in which the identifier appears tells us the part of the structure it references.

```
val x = (1,2);
val x = (1,2) : int * int
val (h,t) = x;
val h = 1 : int
val t = 2 : int
val L = [1, 2, 3];
val L = [1, 2, 3] : int list
val [v1, v2, v3] = L;
val v1 = 1 : int
val v2 = 2 : int
val v3 = 3 : int
val [1, x, 3] = L;
val x = 2 : int
val [1, rest] = L;
(* This is illegal. Why? *)
val yy::rest = L;
val yy = 1 : int
val rest = [2,3] : int list
```

#### Wildcards

An underscore (\_) may be used as a "wildcard" or "don't care" symbol. It matches part of a structure without defining an new binding.

val zz::\_ = L;

val zz = 1 : int
Pattern matching works in records
too.

```
val r = {a=1,b=2};
val r = {a=1,b=2} :
{a:int, b:int}
val {a=va,b=vb} = r;
val va = 1 : int
val vb = 2 : int
val {a=wa,b=_}=r;
val wa = 1 : int
val {a=za, ...}=r;
val za = 1 : int
```

CS 538 Spring 2008

#### PATTERNS CAN be NESTED TOO.

val x = ((1,3.0),5); val x = ((1,3.0),5) : (int \* real) \* int val ((1,y),\_)=x; val y = 3.0 : real

#### **Functions**

CS 538 Spring 2008

261

Functions take a single argument (which can be a tuple).

Function calls are of the form

function\_name argument;

For example

size "xyz";

cos 3.14159;

The more conventional form

size("xyz"); Of cos(3.14159);

is OK (the parentheses around the argument are allowed, but unnecessary).

The form (size "xyz") or (cos 3.14159) is OK too.

# **User-Defined Functions**

The general form is

fun name arg = expression;

ML answers back with the name defined, the fact that it is a function (the **fn** symbol) and its inferred type.

For example,

```
fun twice x = 2*x;
val twice = fn : int -> int
fun twotimes(x) = 2*x;
val twotimes = fn : int -> int
fun fact n =
    if n=0
    then 1
    else n*fact(n-1);
val fact = fn : int -> int
```

# **FUNCTION TYPES**

The type of a function in ML is denoted as **T1->T2**. This says that a parameter of type **T1** is mapped to a result of type **T2**.

The symbol **fn** denotes a value that is a function.

Thus

size; val it = fn : string -> int not; val it = fn : bool -> bool Math.cos;

#### val it = fn : real -> real

(Math is an ML structure—an external library member that contains separately compiled definitions).

CS 538 Spring 2008

fun plus(x,y):int = x+y; val plus = fn : int \* int -> int The :int suffix is a type constraint.

It is needed to help ML decide that + is integer plus rather than real plus.

Patterns In Function Definitions
The following defines a predicate that tests whether a list, <b>L</b> is null (the predefined <b>null</b> function already does this).
<pre>fun isNull L =     if L=[] then true else false;</pre>
<pre>val isNull = fn : 'a list -&gt; bool</pre>
However, we can decompose the definition using <i>patterns</i> to get a simpler and more elegant definition:
fun isNull [] = true
<pre>isNull(_::_) = false; val isNull = fn : 'a list -&gt; bool</pre>

The "|" divides the function definition into different argument patterns; no explicit conditional logic is needed. The definition that matches a particular actual parameter is automatically selected.

fun fact(1) = 1

| fact(n) = n\*fact(n-1);

val fact = fn : int -> int

If patterns that cover all possible arguments aren't specified, you may get a run-time Match exception.

If patterns overlap you may get a warning from the compiler.

CS 538 Spring 2008

269

fun append([],L) = L append(hd::tl,L) = hd::append(t1,L); val append = fn : 'a list \* 'a list -> 'a list If we add the pattern append(L,[]) = Lwe get a redundant pattern warning (Why?) fun append ([],L) = Lappend(hd::tl,L) = hd::append(t1,L) | append(L,[]) = L;stdIn:151.1-153.20 Error: match redundant (nil,L) => ... (hd :: tl,L) => ... (L,nil) => ... -->

CS 538 Spring 2008

## Function Types Can be Polytypes

Recall that 'a, 'b, ... represent type variables. That is, any valid type may be substituted for them when checking type correctness.

ML said the type of **append** is val append = fn : 'a list \* 'a list -> 'a list

Why does 'a appear three times?

We can define **eitherNull**, a predicate that determines whether either of two lists is null as

fun eitherNull(L1,L2) =
 null(L1) orelse null(L2);

val eitherNull =
fn : 'a list \* 'b list -> bool
Why are both 'a and 'b used in
eitherNull's type?

CS 538 Spring 2008

273

# Currying

ML chooses the most general (least-restrictive) type possible for user-defined functions.

Functions are first-class objects, as in Scheme.

The function definition

fun f x y = expression; defines a function f(of x) that returns a function (of y).

Reducing multiple argument functions to a sequence of one argument functions is called *currying* (after Haskell Curry, a mathematician who popularized the approach).

CS 538 Spring 2008

274

#### Thus

fun f x y = x :: [y]; val f = fn : 'a -> 'a -> 'a list says that f takes a parameter x, of type 'a, and returns a function (of y, whose type is 'a) that returns a list of 'a.

Contrast this with the more conventional

fun g(x, y) = x :: [y];

#### val g = fn : 'a \* 'a -> 'a list

Here **g** takes a pair of arguments (each of type **'a**) and returns a value of type **'a** list.

The advantage of currying is that we can bind one argument and leave the remaining argument(s) free.

#### For example

f(1);

is a legal call. It returns a function
of type
fn : int -> int list
The function returned is
equivalent to
fun h b = 1 :: [b];
val h = fn : int -> int list

#### **MAD REVISITED** ML supports the **map** function, which can be defined as fun map(f, []) = []| map(f,x::y) =(f x) :: map(f,y); val map = fn : $('a \rightarrow 'b) * 'a list \rightarrow 'b list$ This type says that **map** takes a pair of arguments. One is a function from type 'a to type 'b. The second argument is a list of type **'a**. The result is a list of type 'b. In curried form **map** is defined as fun map f [] = []| map f (x::y) =(f x) :: map f y; val map = fn : ('a -> 'b) -> 'a list -> 'b list

This type says that **map** takes one argument that is a function from type 'a to type 'b. It returns a function that takes an argument that is a list of type 'a and returns a list of type 'b. The advantage of the curried form of map is that we can now use map to create "specialized" functions in which the function that is mapped is fixed. For example, val neg = map not; val neg = fn : bool list -> bool list neg [true,false,true]; val it = [false,true,false] : bool list

CS 538 Spring 2008

277

Power Sets Revisited

CS 538 Spring 2008

Let's compute power sets in ML. We want a function **pow** that takes a list of values, viewed as a set, and which returns a list of lists. Each sublist will be one of the possible subsets of the original argument.

For example,

pow [1,2] = [[1,2],[1],[2],[]]
We first define a version of cons
in curried form:

fun cons h t = h::t; val cons = fn : 'a -> 'a list -> 'a list Now we define **pow**. We define the powerset of the empty list, [], to be [[]]. That is, the power set of the empty set is set that contains only the empty set.

For a non-empty list, consisting of **h**::t, we compute the power set of t, which we call **pset**. Then the power set for **h**::t is just **h** distributed through **pset** appended to **pset**.

We distribute h through pset very elegantly: we just map the function (cons h) to pset. (cons h) adds h to the head of any list it is given. Thus mapping (cons h) to pset adds h to *all* lists in pset.

```
The complete definition is simply
fun pow [] = [[]]
    pow (h::t) =
 let
     val pset = pow t
    in
    (map (cons h) pset) @ pset
    end;
val pow =
  fn : 'a list -> 'a list list
Let's trace the computation of
pow [1,2].
Here h = 1 and t = [2]. We need
to compute pow [2].
Now h = 2 and t = [].
We know pow [] = [[]],
SO pow [2] =
(map (cons 2) [[]])@[[]] =
([[2]])@[[]] = [[2],[]]
```

```
Therefore pow [1,2] =
 (map (cons 1) [[2],[]])
 ([2],[]]@([2],[]] =
 ([1,2],[1]@([2],[]] =
 ([1,2],[1],[2],[])
```

CS 538 Spring 2008

281

#### **Composing Functions** We can define a composition function that composes two functions into one: fun comp (f,g)(x) = f(g(x));val comp = fn : ('a -> 'b) \* ('c -> 'a) -> 'c -> 'b In curried form we have fun comp f g x = f(g(x));val comp = fn : ('a -> 'b) -> ('c -> 'a) -> 'c -> 'b For example, fun sqr x:int = x\*x; val sqr = fn : int -> int comp sqr sqr; val it = fn : int -> int comp sqr sqr 3;

val it = 81 : int

In SML o (lower-case O) is the infix composition operator. Hence

sqr o sqr  $\equiv$  comp sqr sqr

```
CS 538 Spring 2008
```

#### Polymorphism vs. Overloading

ML supports polymorphism.

A function may accept a polytype (a set of types) rather than a single fixed type.

In all cases, the same function definition is used. Details of the supplied type are irrelevant and may be ignored.

For example,

```
fun id x = x;
val id = fn : 'a -> 'a
fun totist u = ful;
```

```
fun toList x = [x];
val toList = fn : 'a -> 'a list
```

Overloading, as in C++ and Java, allows alternative definitions of the same method or operator, with selection based on type.

Thus in Java + may represent integer addition, floating point addition or string concatenation, even though these are really rather different operations.

In ML +, -, \* and = are overloaded.

When = is used (to test equality), ML deduces that an *equality type* is required. (Most, but not all, types can be compared for equality).

When ML decides an equality type is needed, it uses a type variable that begins with two tics rather than one.

fun eq(x,y) = (x=y);
val eq = fn : ''a \* ''a -> bool

287

CS 538 Spring 2008<sup>®</sup>
# Defining New Types in ML

```
We can create new names for
existing types (type
abbreviations) using
type id = def;
For example,
type triple = int*real*string;
type triple = int * real * string
type rec1=
 {a:int,b:real,c:string};
type rec1 =
  {a:int, b:real, c:string}
type 'a triple3 = 'a*'a*'a;
type 'a triple3 = 'a * 'a * 'a
type intTriple = int triple3;
type intTriple = int triple3
These type definitions are
essentiality macro-like name
substitutions.
```

#### CS 538 Spring 2008

### 289

# The DATATYPE Mechanism

The **datatype** mechanism specifies new data types using value constructors. For example. datatype color = red|blue|green; datatype color = blue | green | red Pattern matching works too using the type's constructors: fun translate red = "rot" translate blue = "blau" translate green = "gruen"; val translate = fn : color -> string fun jumble red = blue jumble blue = green jumble green = red; val jumble = fn : color -> color translate (jumble green); val it = "rot" : string

#### CS 538 Spring 2008

290

# SML EXAMPLES

Source code for most of the SML examples presented here may be found in

~cs538-1/public/sml/class.sml

# **PARAMETERIZED CONSTRUCTORS**

The constructors used to define data types may be parameterized:

```
datatype money =
    none
    | coin of int
    | bill of int
    | iou of real * string;
datatype money =
    bill of int | coin of int
    | iou of real * string | none
Now expressions like coin(25)
```

or bill(5) or iou(10.25, "Lisa") represent valid values of type money.

```
We can also define values and
functions of type money:
val dime = coin(10);
val dime = coin 10 : money
val deadbeat =
iou(25.00, "Homer Simpson");
val deadbeat =
 iou (25.0, "Homer Simpson") :
money
fun amount(none) = 0.0
    amount(coin(cents)) =
     real(cents)/100.0
    amount(bill(dollars)) =
     real(dollars)
    amount(iou(amt,_)) =
     0.5*amt;
 val amount = fn : money -> real
```

### **Polymorphic Datatypes**

A user-defined data type may be polymorphic. An excellent example is

datatype 'a option =
 none | some of 'a;
datatype 'a option =
 none | some of 'a
val zilch = none;
val zilch = none : 'a option
val mucho = some(10e10);
val mucho =
 some 10000000000.0 : real option

type studentInfo =
 {name:string,
 ssNumber:int option};
type studentInfo = {name:string,
 ssNumber:int option}

CS 538 Spring 2008

293

S SSS Spring 2008

val newStudent =
{name="Mystery Man",
 ssNumber=none}:studentInfo;
val newStudent =
{name="Mystery Man",
 ssNumber=none} : studentInfo

# DATATYPES MAY bE RECURSIVE

Recursive datatypes allow linked structures *without* explicit pointers. datatype binTree = null | leaf node of binTree \* binTree; datatype binTree = leaf | node of binTree \* binTree null fun size(null) = 0size(leaf) = 1size(node(t1,t2)) =size(t1)+size(t2) + 1val size = fn : binTree -> int

CS 538 Spring 2008

# RECURSIVE DATATYPES MAY DE Polymorphic

```
datatype 'a binTree =
   null
   leaf of 'a
   node of 'a binTree * 'a binTree
datatype 'a binTree =
   leaf of 'a |
   node of 'a binTree * 'a binTree
   | null
fun frontier(null) = []
   l frontier(leaf(v)) = [v]
   l frontier(node(t1,t2)) =
      frontier(t1) @ frontier(t2)
val frontier =
   fn : 'a binTree -> 'a list
```

We can model n-ary trees by using lists of subtrees:

datatype 'a Tree =
 null
 leaf of 'a
 node of 'a Tree list;
datatype 'a Tree = leaf of 'a |
 node of 'a Tree list | null

fun frontier(null) = []
 frontier(leaf(v)) = [v]
 frontier(node(h::t)) =
 frontier(h) @
 frontier(node(t))
 frontier(node([])) = []
val frontier = fn ;

'a Tree -> 'a list

CS 538 Spring 2008

297

# **Abstract Data Types**

ML also provides abstract data types in which the implementation of the type is *hidden* from users.

The general form is

abstype name = implementation
with

val and fun definitions
end;

Users may access the **name** of the abstract type and the **val** and **fun** definitions that follow the **with**, but the **implementation** may be used only with the body of the **abstype** definition.

# Example

CS 538 Spring 2008

```
abstype 'a stack =
 stk of 'a list
with
  val Null = stk([])
  fun empty(stk([])) = true
      empty(stk(_::_)) = false
  fun top(stk(h::_)) = h
  fun pop(stk(_::t)) = stk(t)
  fun push(v, stk(L)) =
   stk(v::L)
end
type 'a stack
val Null = - : 'a stack
val empty = fn : 'a stack -> bool
val top = fn : 'a stack -> 'a
val pop =
  fn : 'a stack -> 'a stack
val push = fn :
  'a * 'a stack -> 'a stack
```

```
<text><text>
```

```
abstype 'a stack =
 stk of 'a list
with
 local
  fun size(stk(L))=length(L);
 in
  val Null = stk([])
  fun empty(s) =
    (size(s) = 0)
  fun top(stk(h::_)) = h
  fun pop(stk(_::t)) = stk(t)
  fun push(v, stk(L)) =
   stk(v::L)
 end
end
type 'a stack
val Null = - : 'a stack
val empty = fn : 'a stack -> bool
val top = fn : 'a stack -> 'a
val pop = fn :
 'a stack -> 'a stack
val push = fn :
 'a * 'a stack -> 'a stack
```

```
CS 538 Spring 2008
```

Why are abstract data types useful?

Because they hide an implementation of a type from a user, allowing implementation changes without any impact on user programs.

Consider a simple implementation of queues:

```
abstype 'a queue =
  q of 'a list
with
  val Null = q([])
  fun front(q(h::_)) = h
  fun rm(q(_::t)) = q(t)
  fun enter(v,q(L)) =
     q(rev(v::rev(L)))
end
type 'a queue
```

```
type 'a queue
val Null = - : 'a queue
val front = fn : 'a queue -> 'a
```

val rm =
 fn : 'a queue -> 'a queue
val enter =
 fn : 'a \* 'a queue -> 'a queue

This implementation of queues is valid, but somewhat inefficient. In particular to enter a new value onto the rear end of a queue, we do the following:

```
fun enter(v,q(L)) =
   q(rev(v::rev(L)))
```

We reverse the list that implements the queue, add the new value to the head of the reversed queue *then* reverse the list a second time.

```
303
```

A more efficient (but less obvious) implementation of a queue is to store it as two lists. One list represents the "front" of the queue. It is from this list that we extract the front value, and from which we remove elements.

The other list represents the "back" of the queue (in reversed order). We add elements to the rear of the queue by adding elements to the front of the list. From time to time, when the front list becomes null, we "promote" the rear list into the front list (by reversing it). Now access to both the front and the back of the queue is fast and direct. The new implementation is:

```
abstype 'a queue =
  q of 'a list * 'a list
with
  val Null = q([],[])
  fun front(q(h::_{/})) = h
      front(q([],L)) =
        front(q(rev(L),[]))
  fun rm(q(\_::t,L)) = q(t,L)
   | rm(q([],L)) =
        rm(q(rev(L), []))
  fun enter(v,q(L1,L2)) =
     q(L1, v::L2)
end
type 'a queue
val Null = - : 'a queue
val front = fn :
  'a queue -> 'a
val rm = fn :
 'a queue -> 'a queue
val enter = fn :
 'a * 'a queue -> 'a queue
```

CS 538 Spring 2008

From the user's point of view, the two implementations are *identical* (they export exactly the same set of values and functions). Hence the new implementation can replace the old implementation without any impact at all to the user (except, of course, performance!).

# **Exception Handling**

CS 538 Spring 2008

305

Our definitions of stacks and queues are incomplete. Reconsider our definition of stack: abstype 'a stack = stk of 'a list with val Null = stk([]) fun empty(stk([])) = true empty(stk(\_::\_)) = false fun top(stk(h::\_)) = h fun pop(stk(\_::t)) = stk(t) fun push(v, stk(L)) =stk(v::L) end What happens if we evaluate top(Null);

CS 538 Spring 2008

307

CS 538 Spring 2008

We see "match failure" since our definition of top is incomplete!

In ML we can *raise* an exception if an illegal or unexpected operation occurs. Asking for the top of an empty stack ought to raise an exception since the requested value does not exist.

ML contains a number of predefined exceptions, including

Match Empty Div Overflow (exception names usually begin with a capital letter).

Predefined exception are raised by illegal values or operations. If they are not caught, the runtime prints an error message.

```
fun f(1) = 2;
val f = fn : int -> int
f(2);
uncaught exception nonexhaustive
match failure
hd [];
uncaught exception Empty
1000000*1000000;
uncaught exception overflow
(1 div 0);
uncaught exception divide by zero
1.0/0.0;
val it = inf : real
(inf is the IEEE floating-point
standard "infinity" value)
```

CS 538 Spring 2008

309

CS 538 Spring 2008<sup>®</sup>

# **User Defined Exceptions**

New exceptions may be defined as exception name; Or exception name of type; For example exception IsZero; exception IsZero exception NegValue of real; exception NegValue of real

# **EXCEPTIONS MAY DE RAISED**

```
val sqrt = Real.Math.sqrt;
val sqrt = fn : real -> real
fun sqroot(x) =
if x < 0.0
then raise NegValue(x)
else sqrt(x);
val sqroot = fn : real -> real
sqroot(2.0);
val it = 1.41421356237 : real
sqroot(~2.0);
uncaught exception NegValue
```

# **Exception Handlers**

CS 538 Spring 2008

314

# **STACKS REVISITED**

We can add an exception, Emptystk, to our earlier stack type to handle top or pop operations on an empty stack: abstype 'a stack = stk of 'a list with val Null = stk([]) exception EmptyStk fun empty(stk([])) = true empty(stk(\_::\_)) = false fun top(stk(h::\_)) = h top(stk([])) =raise EmptyStk fun pop(stk(\_::t)) = stk(t) pop(stk([])) =Т raise EmptyStk fun push(v,stk(L)) = stk(v::L) end

```
type 'a stack
val Null = - : 'a stack
exception EmptyStk
val empty = fn : 'a stack -> bool
val top = fn : 'a stack -> 'a
val pop = fn :
  'a stack -> 'a stack
val push = fn : 'a * 'a stack ->
  'a stack
pop(Null);
uncaught exception EmptyStk
top(Null) handle EmptyStk => 0;
val it = 0 : int
```

User-Defined Operators
<ul> <li>SML allows users to define symbolic operators composed of non-alphanumeric characters. This means operator-like symbols can be created and used. Care must be taken to avoid predefined operators (like +, -, ^, @, etc.).</li> <li>If we wish, we can redo our stack definition using symbols rather than identifiers. We might use the following symbols:</li> </ul>
top  =
pop <==
push ==>
null <@>
empty
6

We can have expressions like <?> <@>; val it = true : bool |= (==> (1, <@>));val it = 1 : int Binary functions, like ==> (push) are much more readable if they are infix. That is, we'd like to be able to write 1 ==> 2+3 ==> <@> which pushes 2+3, then 1 onto an empty stack. To make a function (either identifier or symbolic) infix rather than prefix we use the definition infix level name or

infixr level name

CS 538 Spring 2008

317

CS 538 Spring 2008

level is an integer representing the "precedence" level of the infix operator. o is the lowest precedence level; higher precedence operators are applied before lower precedence operators (in the absence of explicit parentheses).

infix defines a left-associative operator (groups from left to right). infixr defines a rightassociative operator (groups from right to left).

Thus

fun cat(L1,L2) = L1 @ L2; infix 5 cat

makes cat a left associative infix operator at the same

precedence level as **e**. We can now write

[1,2] cat [3,4,5] cat [6,7]; val it = [1,2,3,4,5,6,7] : int list The standard predefined operators have the following precedence levels:

Level Operator

3	ο					
4	=	<>	<	>	<=	>=
5	::	e				
6	+	-	^			
7	*	/	div	mo	bđ	

```
If we define =⇒ (push) as
infixr 2 =>
then
1 => 2+3 =⇒ <€>
will work as expected,
evaluating expressions like 2+3
before doing any pushes, with
pushes done right to left
```

```
abstype 'a stack =
  stk of 'a list
with
   val <@> = stk([])
   exception emptyStk
   fun <?>(stk([])) = true
       <?>(stk( :: )) = false
    fun |=(stk(h::_)) = h
      |=(stk([])) =
    raise emptyStk
   fun <==(stk(::t)) = stk(t)
      <==(stk([])) =
          raise emptyStk
   fun =>(v, stk(L)) =
            stk(v::L)
   infixr 2 ==>
end
```

CS 538 Spring 2008

type 'a stack val  $\langle e \rangle = - : 'a stack$ exception emptyStk val <?> = fn : 'a stack -> bool val |= = fn : 'a stack -> 'a val  $\leq = = fn :$ 'a stack -> 'a stack val => = fn : 'a \* 'a stack >'a stack infixr 2 ==> Now we can write val myStack = 1 => 2+3 => <@>;val myStack = - : int stack = myStack; val it = 1 : int |= (<== myStack);</pre> val it = 5 : int

## Using Infix Operators as Values

Sometimes we simply want to use an infix operator as a symbol whose value is a function. For example, given fun dupl f v = f(v,v);val dupl = fn : ('a \* 'a -> 'b) -> 'a -> 'b we might try the call dupl ^ "abc"; This fails because SML tries to parse dup1 and "abc" as the operands of **^**. To pass an operator as an ordinary function value, we prefix it with op which tells the

CS 538 Spring 2008

# THE CASE EXPRESSION

ML contains a case expression patterned on switch and case statements found in other languages.

As in function definitions, patterns are used to choose among a variety of values.

The general form of the case is case expr of

pattern<sub>1</sub> => expr<sub>1</sub>|
pattern<sub>n</sub> => expr<sub>2</sub>|

...
pattern<sub>n</sub> => expr<sub>n</sub>;

If no pattern matches, a Match exception is thrown.

CS 538 Spring 2008

It is common to use (the wildcard) as the last pattern in d case. **Examples** include case c of red => "rot" | blue => "blau" | green => "gruen"; case pair of (1,\_) => "win" | (2,\_) => "place" | (3,\_) => "show" | ( , ) => "loser"; case intOption of none  $\Rightarrow 0$  $some(v) \Rightarrow v;$ 

# IMPERATIVE FEATURES OF ML

ML provides references to heap locations that may be updated. This is essentially the same as access to heap objects via references (Java) or pointers (C and C++).

The expression

ref val

creates a reference to a heap location initialized to val. For example,

ref 0;

```
val it = ref 0 : int ref
```

The prefix operator ! fetches the value contained in a heap location (just as \* dereferences a pointer in C or C++).

```
Thus
 ! (ref 0);
 val it = 0 : int
The expression
ref := val
updates the heap location
referenced by ref to contain
val. The unit value, (), is
returned.
Hence
val x = ref 0;
val x = ref 0 : int ref
!x:
val it = 0 : int
x:=1;
val it = () : unit
!x:
val it = 1 : int
```

# **SEQUENTIAL COMPOSITION**

Expressions or statements are sequenced using ";". Hence val a = (1+2;3+4); val a = 7 : int (x:=1;!x); val it = 1 : int

# ITERATION

while expr1 do expr2 implements iteration (and returns unit); Thus (while false do 10); val it = () : unit while !x > 0 do x:= !x-1; val it = () : unit !x; val it = 0 : int

CS 538 Spring 2008

```
Simple I/O
  The function
   print;
   val it = fn : string -> unit
  prints a string onto standard
  output.
  For example,
   print("Hello World\n");
   Hello World
  The conversion routines
   Real.toString;
   val it = fn : real -> string
   Int.toString;
   val it = fn : int -> string
   Bool.toString;
   val it = fn : bool -> string
```

convert a value (rea1, int or boo1) into a string. Unlike Java, the call must be explicit.

For example,

print(Int.toString(123));

```
123
```

CS 538 Spring 2008

329

Also available are

Real.fromString;

val it = fn : string -> real
option
Int.fromString;
val it = fn : string -> int
option

Bool.fromString;

val it = fn : string -> bool
option

which convert from a string to a real Or int Or bool *if possible*. (That's why the option type is used).

331

# Τεχτ Ι/Ο

The structure **TextIO** contains a wide variety of I/O types, values and functions. You load these by entering:

### open TextIO;

Among the values loaded are

- type instream This is the type that represents input text files.
- type outstream This is the type that represents output text files.
- type vector = string Makes vector a synonym for string.
- type elem = char Makes elem a synonym for char.

CS 538 Spring 2008

333

334

```
•val stdIn : instream
 val stdOut : outstream
 val stdErr : outstream
 Predefined input & output streams.
• val openIn :
  string -> instream
 val openOut :
  string -> outstream
 Open an input or output stream.
 For example,
 val out =
  openOut("/tmp/test1");
 val out = - : outstream
.val input :
   instream -> vector
 Read a line of input into a string
 (vector is defined as equivalent to
 string). For example (user input is
 in red):
 val s = input(stdIn);
 Hello!
  val s = "Hello!\n" : vector
```

.val inputN : instream \* int -> vector Read the next **n** input characters into a **string**. For example, val t = inputN(stdIn,3); abcde val t = "abc" : vector • val inputAll : instream -> vector Read the rest of the input file into a **string** (with newlines separating lines). For example, val u = inputAll(stdIn); Four score and seven years ago ... val u = "Four score and\nseven years ago ... \n" : vector • val endOfStream : instream -> bool Are we at the end of this input stream?

**String Operations** 

ML provides a wide variety of string manipulation routines. Included are:

- The string concatenation operator,
   ^ "abc" ^ "def" = "abcdef"
- The standard 6 relational operators:
   <=>==<>
- The string size operator:
  val size : string -> int
  size ("abcd");
  val it = 4 : int
  The string subscripting operator
- . The string subscripting operator
  (indexing from 0):
   val sub =
   fn : string \* int -> char
   sub("abcde",2);
   val it = #"c" : char

CS 538 Spring 2008

338

• The substring function val substring : string \* int \* int -> string This function is called as substring(string, start, len) **start** is the starting position, counting from 0. **len** is the length of the desired substring. For example, substring("abcdefghij",3,4) val it = "defg" : string Concatenation of a list of strings into a single string: concat : string list -> string For example, concat ["What's"," up","?"]; val it = "What's up?" : string

```
• Convert a character into a string:
 str : char -> string
 For example,
  str(#"x");
  val it = "x" : string
• "Explode" a string into a list of
 characters:
 explode : string -> char list
 For example,
 explode("abcde");
 val it =
 [#"a",#"b",#"c",#"d",#"e"] :
 char list
• "Implode" a list of characters into a
 string.
 implode : char list -> string
 For example,
 implode
 [#"a", #"b", #"c", #"d", #"e"];
 val it = "abcde" : string
```

### Structures and Signatures

In C++ and Java you can group variable and function definitions into classes. In Java you can also group classes into packages.

In ML you can group value, exception and function definitions into *structures*.

You can then import selected definitions from the structure (using the notation structure.name) Or YOU Can open the structure, thereby importing all the definitions within the structure.

(Examples used in this section may be found at

~cs538-1/public/sml/struct.sml)

CS 538 Spring 2008

341

The general form of a structure

if key = key1
then value1
else lookup(key,rest);

CS 538 Spring 2008

342

```
fun insert(key,value,[]) =
                [(key,value)]
     insert(key,value,
         (key1,value1)::rest) =
      if key = key1
      then (key, value) :: rest
      else (key1,value1)::
            insert(key,value,rest);
end;
We can access members of this
structure as Mapping.name. Thus
Mapping.insert(538, "languages", []);
val it = [(538, "languages")] :
(int * string) list
open Mapping;
exception NotFound
val create : 'a list
val insert : ''a * 'b * (''a * 'b)
 list -> (''a * 'b) list
val lookup : ''a * (''a * 'b)
 list -> 'b
```

SiqNATURES
Each structure has a signature,
which is it type.
For example, Mapping's
signature is
structure Mapping :
 sig
 exception NotFound
 val create : 'a list
 val insert : ''a \* 'b \*
 (''a \* 'b) list ->
 (''a \* 'b) list

val lookup : ''a \*

(''a \* 'b) list -> 'b

end

```
You can define a signature as
signature name = sig
type definitions for values,
functions and exceptions
end
For example,
signature Str2IntMapping =
sig
exception NotFound;
val lookup:
string * (string*int) list
c; int;
end;
```

```
Signatures can be used to
Restrict the type of a value or function in a structure.
Hide selected definitions that appear in a structure
For example
structure Str2IntMap :
Str2IntMapping = Mapping;
defines a new structure,
str2IntMap, created by
restricting Mapping to the
str2IntMapping Signature. When we do this we get
```

open Str2IntMap; exception NotFound val lookup : string \* (string \* int) list -> int

Only lookup and NotFound are created, and lookup is limited to keys that are strings.

# Extending ML's Polymorphism

In languages like C++ and Java we must use types like void\* or object to simulate the polymorphism that ML provides. In ML whenever possible a general type (a polytype) is used rather than a fixed type. Thus in

```
fun len([]) = 0
    | len(a::b) = 1 + len(b);
We get a type of
```

### 'a list -> int

because this is the most general type possible that is consistent with len's definition. Is this form of polymorphism general enough to capture the

```
general idea of making
program definitions as type-
independent as possible?
It isn't, and to see why consider
the following ML definition of a
merge sort. A merge sort
operates by first splitting a list
into two equal length sublists.
The following function does
this:
fun split [] = ([],[])
   split [a] = ([a],[])
    split (a::b::rest) =
    let val (left,right) =
      split(rest) in
       (a::left, b::right)
    end;
```

```
After the input list is split into
two halves, each half is
recursively sorted, then the
sorted halves are merged
together into a single list.
```

The following ML function merges two sorted lists into one:

```
CS 538 Spring 2008
```

349

With these two subroutines, a definition of a sort is easy:

```
fun sort [] = []
| sort([a]) = [a]
| sort(a::b::rest) =
    let val (left,right) =
        split(a::b::rest) in
        merge(sort(left),
            sort(right))
```

end;

CS 538 Spring 2008

This definition looks very general—it should work for a list of any type.

Unfortunately, when ML types the functions we get a surprise:

```
val split = fn : 'a list ->
  'a list * 'a list
val merge = fn : int list *
  int list -> int list
val sort = fn :
```

```
int list -> int list
split is polymorphic, but merge
```

and sort are limited to integer lists!

Where did this restriction come from?

```
The problem is that we did a
comparison in merge using the
<= operator, and ML typed this
as an integer comparison.
We can make our definition of
sort more general by adding a
comparison function, le(a,b)
as a parameter to merge and
sort. If we curry this parameter
we may be able to hide it from
end users. Our updated
definitions are:
fun merge(1e, [], []) = []
   merge(le,[],hd::tl) = hd::tl
   merge(le,hd::tl,[]) = hd::tl
   merge(le,hd::tl,h::t) =
    if le(hd,h)
    then hd::merge(le,tl,h::t)
    else h::merge(le,hd::tl,t)
```

```
fun sort le [] = []
   sort le [a] = [a]
    sort le (a::b::rest) =
     let val (left,right) =
       split(a::b::rest) in
         merge(le, sort le left,
                   sort le right)
     end;
Now the types of merge and
sort are:
val merge = fn :
 ('a * 'a -> bool) *
  'a list * 'a list -> 'a list
val sort = fn : ('a * 'a -> bool)
      -> 'a list -> 'a list
We can now "customize" sort
by choosing a particular
definition for the 1e parameter:
fun le(a,b) = a <= b;
val le = fn : int * int -> bool
```

```
CS 538 Spring 2008
```

353

CS 538 Spring 2008

```
fun intsort L = sort le L;
val intsort =
  fn : int list -> int list
intsort(
 [4,9,0,2,111,~22,8,~123]);
val it = [~123,~22,0,2,4,8,9,111]
: int list
fun strle(a:string,b) =
   a <= b;
val strle =
  fn : string * string -> bool
fun strsort L = sort strle L;
val strsort =
 fn : string list -> string list
strsort(
  ["aac","aaa","ABC","123"]);
val it =
["123", "ABC", "aaa", "aac"] :
string list
```

Making the comparison relation an explicit parameter works, but it is a bit ugly and inefficient. Moreover, if we have several functions that depend on the comparison relation, we need to ensure that they all use the same relation. Thus if we wish to define a predicate inorder that tests if a list is already sorted, we can use: fun inorder le [] = true

```
| inOrder le [a] = true
| inOrder le (a::b::rest) =
    le(a,b) andalso
        inOrder le (b::rest);
val inOrder = fn :
```

### ('a \* 'a -> bool) -> 'a list -> bool

Now sort and inorder need to use the same definition of 1e. But how can we enforce this?

```
The structure mechanism we
studied earlier can help. We can
put a single definition of 1e in
the structure, and share it:
structure Sorting =
struct
  fun le(a,b) = a <= b;
  fun split [] = ([],[])
      split [a] = ([a],[])
      split (a::b::rest) =
      let val (left,right) =
        split rest in
         (a::left,b::right)
      end;
  fun merge([], []) = []
      merge([],hd::tl) = hd::tl
      merge(hd::tl,[]) = hd::tl
      merge(hd::tl,h::t) =
      if le(hd,h)
      then hd::merge(t1,h::t)
      else h::merge(hd::tl,t)
```

```
fun sort [] = []
     sort([a]) = [a]
      sort(a::b::rest) =
      let val (left,right) =
        split(a::b::rest) in
         merge(sort(left)
               sort(right))
      end:
  fun inOrder [] = true
     inOrder [a] = true
      inOrder (a::b::rest) =
       le(a,b) andalso
        inOrder (b::rest);
end;
structure Sorting :
 sig
  val inOrder : int list -> bool
  val le : int * int -> bool
   val merge : int list *
     int list -> int list
    val sort :
      int list -> int list
    val split : 'a list ->
     'a list * 'a list
  end
```

357

To sort a type other than integers, we replace the definition of 1e in the structure.

But rather than actually edit that definition, ML gives us a powerful mechanism to parameterize a structure. This is the *functor*, which allows us to use one or more structures as parameters in the definition of a structure.

### **FUNCTORS**

CS 538 Spring 2008

The general form of a functor is

functor name
(structName:signature) =
 structure definition;

This functor will create a specific version of the structure definition using the structure parameter passed to it.

For our purposes this is ideal we pass in a structure defining an ordering relation (the 1e function). This then creates a custom version of all the functions defined in the structure body, using the specific 1e definition provided.

CS 538 Spring 2008

359

```
We first define
signature Order =
sig
  type elem
  val le : elem*elem -> bool
end;
This defines the type of a
structure that defines a 1e
predicate defined on a pair of
types called elem.
An example of such a structure
İS
structure IntOrder:Order =
struct
  type elem = int;
  fun le(a,b) = a <= b;
end;
```

```
Now we just define a functor
that creates a sorting structure
based on an order structure:
functor MakeSorting(0:Order) =
struct
 open 0; (* makes le available*)
  fun split [] = ([],[])
      split [a] = ([a],[])
      split (a::b::rest) =
      let val (left,right) =
        split rest in
         (a::left,b::right)
      end;
  fun merge([], []) = []
     merge([],hd::tl) = hd::tl
     merge(hd::tl,[]) = hd::tl
     merge(hd::tl,h::t) =
      if le(hd,h)
      then hd::merge(tl,h::t)
      else h::merge(hd::tl,t)
```

```
CS 538 Spring 2008
```

```
361
```

```
fun sort [] = []
      sort([a]) = [a]
      sort(a::b::rest) =
      let val (left,right) =
       split(a::b::rest) in
        merge(sort(left),
              sort(right))
      end;
  fun inOrder [] = true
      inOrder [a] = true
      inOrder (a::b::rest) =
       le(a,b) andalso
         inOrder (b::rest);
end;
```

CS 538 Spring 2008

```
Now
structure IntSorting =
MakeSorting(IntOrder);
creates a custom structure for
sorting integers:
 IntSorting.sort [3,0,~22,8];
val it = [~22,0,3,8] : elem list
To sort strings, we just define a
structure containing an 1e
defined for strings with order
as its signature (i.e., type) and
pass it to MakeSorting:
structure StrOrder:Order =
struct
  type elem = string
  fun le(a:string,b) = a <= b;</pre>
end;
```

```
structure StrSorting =
  MakeSorting(StrOrder);
StrSorting.sort(
 ["cc","abc","xyz"]);
val it = ["abc","cc","xyz"] :
 StrOrder.elem list
StrSorting.inOrder(
 ["cc", "abc", "xyz"]);
val it = false : bool
StrSorting.inOrder(
 [3,0,~22,8]);
stdIn:593.1-593.32 Error:
operator and operand don't agree
[literal]
  operator domain: strOrder.elem
list
                   int list
  operand:
  in expression:
   StrSorting.inOrder (3 :: 0 ::
~22 :: <exp> :: <exp>)
```

# THE SML BASIS LIBRARY

SML provides a wide variety of useful types and functions, grouped into structures, that are included in the *Basis Library*.

A web page fully documenting the Basis Library is linked from the ML page that is part of the Programming Languages Links page on the CS 538 home page.

Many useful types, operators and functions are "preloaded" when you start the SML compiler. These are listed in the "Top-level Environment" section of the Basis Library documentation.

CS 538 Spring 2008

Many other useful definitions must be explicitly fetched from the structures they are defined in.

For example, the Math structure contains a number of useful mathematical values and operations.

You may simply enter

### open Math;

while will load all the definitions in Math. Doing this may load more definitions than you want. What's worse, a definition loaded may redefine a definition you currently want to stay active. (Recall that ML has virtually no overloading, so functions with the same name in different structures are common.)

A more selective way to access a definition is to qualify it with the structure's name. Hence

### Math.pi;

CS 538 Spring 2008

365

val it = 3.14159265359 : real

gets the value of pi defined in Math.

Should you tire of repeatedly qualifying a name, you can (of course) define a local value to hold its value. Thus

val pi = Math.pi; val pi = 3.14159265359 : real works fine.

367

# An Overview of Structures in the Basis Library

The Basis Library contains a wide variety of useful structures. Here is an overview of some of the most important ones.

- **Option** Operations for the **option** type.
- Bool

Operations for the **bool** type.

- **Char** Operations for the **char** type.
- String

Operations for the **string** type.

• Byte

Operations for the **byte** type.

CS 538 Spring 2008

• Int

Operations for the **int** type.

- IntInf
   Operations for an unbounded
   precision integer type.
- **Real** Operations for the **real** type.
- Math
   Various mathematical values and operations.
  - List
    - Operations for the **list** type.
- ListPair
  - Operations on pairs of lists.
- Vector A polymorphic type for immutable (unchangeable) sequences.

CS 538 Spring 2008

369

370

- IntVector, RealVector, BoolVector, CharVector Monomorphic types for immutable sequences.
- **Array** A polymorphic type for mutable (changeable) sequences.
- IntArray, RealArray, BoolArray, CharArray
   Monomorphic types for mutable

sequences.

- Array2 A polymorphic 2 dimensional mutable type.
- IntArray2, RealArray2, BoolArray2, CharArray2
   Monomorphic 2 dimensional mutable types.
- TextIO Character-oriented text IO.

- BinIO
  - Binary IO operations.
- OS, Unix, Date, Time, Timer Operating systems types and operations.

# **ML** Type Inference

One of the most novel aspects of ML is the fact that it infers types for all user declarations.

How does this type inference mechanism work?

Essentially, the ML compiler creates an unknown type for each declaration the user makes. It then solves for these unknowns using known types and a set of type inference rules. That is, for a user-defined identifier 1, ML wants to determine  $\tau(i)$ , the type of i.

The type inference rules are:

1. The types of all predefined literals, constants and functions are known in advance. They may be looked-up and used. For example,

2 : int true : bool [] : 'a list :: : 'a \* 'a list -> 'a list 2. All occurrences of the same symbol (using scoping rules) have

3. In the expression I = Jwe know  $\mathbf{T}(\mathbf{I}) = \mathbf{T}(\mathbf{J})$ .

the same type.

CS 538 Spring 2008

CS 538 Spring 2008

373

374

4. In a conditional (if E1 then E2 else E3) we know that T(E1) = bool,T(E2) = T(E3) = T(conditional)5. In a function call (f x)we know that if  $T(f) = a \rightarrow b$ then  $\mathbf{T}(\mathbf{x}) = \mathbf{a}$  and  $\mathbf{T}(\mathbf{f} \mathbf{x}) = \mathbf{b}$ 6. In a function definition fun f x = expr;if t(x) = a and T(expr) = bthen  $\mathbf{T}(\mathbf{f}) = \mathbf{a} \rightarrow \mathbf{b}$ 7. In a tuple  $(e_1, e_2, ..., e_n)$ if we know that  $T(e_i) = 'a_i \ 1 \le i \le n$ then  $T(e_1, e_2, ..., e_n) =$ 'a<sub>1</sub>\*'a<sub>2</sub>\*...\*'a<sub>n</sub>

8. In a record { a=e<sub>1</sub>, b=e<sub>2</sub>, ... } if  $\mathbf{T}(\mathbf{e}_i) = \mathbf{a}_i \quad 1 \leq i \leq n$  then the type of the record = $\{a: a_1, b: a_2, \ldots\}$ 9. In a list  $[v_1, v_2, \dots, v_n]$ if we know that  $\mathbf{T}(\mathbf{v}_i) = \mathbf{a}_i \quad 1 \leq i \leq n$ then we know that  $a_1 = a_2 = \ldots = a_n$  and  $T([v_1, v_2, ..., v_n]) = 'a_1$  list

# To Solve for Types:

- 1. Assign each untyped symbol its own distinct type variable.
- 2.Use rules (1) to (9) to solve for and simplify unknown types.
- 3. Verify that each solution "works" (causes no type errors) throughout the program.

# Examples

Consider

fun fact(n)=
 if n=1 then 1 else n\*fact(n-1);
To begin, we'll assign type
variables:

```
T(fact) = 'a -> 'b
(fact is a function)
T(n) = 'c
```

CS 538 Spring 2008

Now we begin to solve for the types 'а, 'ь and 'с must represent.

We know (rule 5) that c = a since n is the argument of fact.

We know (rule 3) that 'c = T(1) = int since n=1 is part of the definition.

We know (rule 4) that T(1) = T(if expression) = b since the if expression is the body of fact.

Thus, we have

a = b = c = int, SO

 $T(fact) = int \rightarrow int$ 

T(n) = int

These types are correct for all occurrences of fact and n in the definition.

CS 538 Spring 2008

377

# A Polymorphic Function:

```
fun leng(L) =
    if L = []
    then 0
    else 1+len(tl L);
To begin, we know that
T([]) = 'a list and
T(tl) = 'b list -> 'b list
We assign types to leng and L:
T(leng) = 'c -> 'd
T(L) = 'e
Since L is the argument of leng,
    'e = 'c
From the expression L=[] we
know
'e = 'a list
```

From the fact that o is the result of the then, we know the if returns an int, so 'd = int.

Thus T(leng) = 'a list -> intand

T(L) = 'a list

These solutions are type correct throughout the definition.

# **Type Inference for Patterns**

```
Type inference works for
patterns too.
Consider
fun leng [] = 0
    leng (a::b) = 1 + leng b;
 We first create type variables:
T(leng) = 'a -> 'b
T(a) = 'c
T(b) = 'd
From leng [] we conclude that
'a = 'e list
From leng [] = 0 we conclude
that
b = int
From leng (a::b) we conclude
that
```

```
'c ='e and 'd = 'e list
Thus we have
T(leng) = 'e list -> int
T(a) = 'e
T(b) = 'e list
This solution is type correct
throughout the definition.
```

```
CS 538 Spring 2008
```

381

CS 538 Spring 2008

as an argument—the type system doesn't allow it. In Scheme this is allowed: (define (f x) (x x)) but a call like (f f) certainly doesn't do anything good!

Let's try to type fun f x = (x x);

Not Everything can be

AUTOMATICALLY TYPED IN ML

```
We assume
T(f) = 'a -> 'b
```

```
t(x) = 'c
Now (as usual) 'a = 'c since x is
the argument of f.
```

```
From the call (x x) we conclude
that 'c must be of the form 'd ->
'e (since x is being used as a
function).
```

```
Moreover, c = d since x is an argument in (x x).
```

```
Thus 'c = 'd ->'e = 'c ->'e.
```

```
But 'c = 'c->'e has no solution,
so in ML this definition is invalid.
We can't pass a function to itself
```

CS 538 Spring 2008

383

# **Type Unions**

Let's try to type fun f g = ((g 3), (g true));Now the type of g is 'a -> 'b since a is used as a function. The call ( $\mathbf{q}$  3) says  $\mathbf{a} = \mathbf{int}$  and the call (g true) says 'a = boolean. Does this mean g is polymorphic? That is, is the type of **f** f : ('a->'b)->'b\*'b? NO! All functions have the type 'a -> ъ but not all functions can be passed to **f**. Consider not: bool->bool. The call (not 3) is certainly illegal.

What we'd like in this case is a *union* type. That is, we'd like to be able to type g as (int|bool)->'b which ML doesn't allow. Fortunately, ML does allow type constructors, which are just what we need. Given datatype T = I of int | B of bool; we can redefine **f** as fun f g =(g (I(3)), g (B(true))); val f = fn :  $(T \rightarrow a) \rightarrow a \ast a$ 

CS 538 Spring 2008

385

CS 538 Spring 2008

Finally, note that in a definition like let val f = fn  $x \Rightarrow x$  (\* id function\*) in (f 3,f true) end; type inference works fine: val it = (3,true) : int \* bool Here we define f in advance, so its type is known when calls to it are seen.

# Prolog

Prolog presents a view of programming that is very different from most other programming languages.

A famous text book is entitled "Algorithms + Data Structures = Programs"

This formula represents well the conventional approach to programming that most programming languages support.

In Prolog there is an alternative rule of programming:

"Algorithms = Logic + Control"

This rule encompasses a *non-procedural* view of programming. Logic (what the program is to compute) comes first.

CS 538 Spring 2008

Then control (how to implement the logic) is considered.

In Prolog we program the logic of a program, but the Prolog system *automatically* implements the control.

Logic is essential—control is just efficiency.

CS 538 Spring 2008

389

# Logic Programming

Prolog implements *logic programming*.

In fact Prolog means **Pro**gramming in **Log**ic.

In Prolog programs are statements of rules and facts.

Program execution is deduction—can an answer be inferred from known rules and facts.

Prolog was developed in 1972 by Kowalski and Colmerauer at the University of Marseilles.

# Elementary Data Objects

- In Prolog *integers* and *atoms* are the elementary data objects.
- Integers are ordinary integer literals and values.
- *Atoms* are identifiers that begin with a lower-case letter (much like symbolic values in Scheme).
- In Prolog data objects are called *terms*.
- In Prolog we define *relations* among terms (integers, atoms or other terms).
- A *predicate* names a relation. Predicates begin with lower-case letters.
- To define a predicate, we write *clauses* that define the relation.

- There are two kinds of program clauses, *facts* and *rules*.
- A fact is a predicate that prefixes a sequence of terms, and which ends with a period (".").

As an example, consider the following facts which define "fatherOf" and "motherOf" relations.

fatherOf(tom,dick).
fatherOf(dick,harry).
fatherOf(jane,harry).
motherOf(tom,judy).
motherOf(dick,mary).
motherOf(jane,mary).

The symbols fatherof and motherof are predicates. The symbols tom, dick, harry, judy, mary and jane are atoms. Once we have entered rules and facts that define relations, we can make queries (ask the Prolog system questions).

Prolog has two interactive modes that you can switch between.

To enter *definition mode* (to define rules and facts) you enter

### [user].

You then enter facts and rules, terminating this phase with **^D** (end of file).

Alternatively, you can enter

### ['filename'].

to read in rules and facts stored in the file named filename.

CS 538 Spring 2008

393

When you start Prolog, or after you leave definitions mode, you are in *query mode*.

In query mode you see a prompt of the form

| ?- Or ?- (depending on the system you are running).

In query mode, Prolog allows you to ask whether a relation among terms is *true* or *false*.

Thus given our definition of **motherOf** and **fatherOf** relations, we can ask:

# | ?- fatherOf(tom,dick). yes

A "yes" response means that Prolog is able to conclude from the facts and rules it has been given that the relation queried does hold.

# | ?- fatherOf(georgeW,george). no

A "no" response to a query means that Prolog is unable to conclude that the relation holds from what it has been told. The relation may actually be true, but Prolog may lack necessary facts or rules to deduce this.

CS 538 Spring 2008

If no solution can be found, it tells us so:

```
?- fatherOf(Y,jane).
```

### no

Since solutions to queries need not be unique, Prolog will give us alternate solutions if we ask for them. We do so by entering a ";" after a solution is printed. We get a "no" when no more solutions can be found:

```
?- fatherOf(X,harry).
```

```
X = dick;
```

```
X = jane;
```

no

CS 538 Spring 2008

397

```
CS 538 Spring 2008
```

398

Variables may be placed anywhere in a query. Thus we may ask

```
?- fatherOf(jane,X).
```

```
X = harry ;
```

### no

We may use more than one variable if we wish:

Y = harry ;

```
X = jane,
```

```
Y = harry ;
```

```
no
```

(This query displays all the **fatherOf** relations).

# **CONJUNCTION OF GOALS**

More than one relation can be included as the "goal" of a query. A comma (",") is used as an AND operator to indicate a conjunction of goals—all must be satisfied by a solution to the query.

| ?fatherOf(jane,X),motherOf(jane,Y).

```
X = harry,
```

```
Y = mary ;
```

no

A given variable may appear more than once in a query. The same value of the variable must be used in all places in which the variable appears (this is called *unification*).

```
For example,
| ?-
fatherOf(tom, X), fatherOf(X, harry).
X = dick;
no
```

### **Rules in Prolog** Rules allow us to state that a relation will hold depending on the truth (correctness) of other relations. In effect a rules says, "If I know that certain relations hold, then I also know that this relation holds.' A rule in Prolog is of the form $rel_1 := rel_2, rel_3, \ldots rel_n.$ This says **rel**<sup>1</sup> can be assumed true if we can establish that **rel**<sub>2</sub> and **rel**<sub>3</sub> and all relations to **rel**<sub>n</sub> are true. **rel**<sub>1</sub> is called the *head* of the rule. **rel**<sub>2</sub> to **rel**<sub>n</sub> form the *body* of the rule.

CS 538 Spring 2008

401

# EXAMPLE

The following two rules define a grandMotherOf relation using the motherOf and fatherOf relations:

grandMotherOf(X,GM) :-

```
motherOf(X,M),
```

```
motherOf(M,GM).
grandMotherOf(X,GM) :-
```

```
fatherOf(X,F),
 motherOf(F,GM).
```

```
?- grandMotherOf(tom,GM).
```

```
GM = mary ;
no
```

```
?- grandMotherOf(dick,GM).
```

```
no
?- grandMotherOf(X,mary).
```

```
X = tom ;
```

As is the case for all programming, in all languages, you must be careful when you define a rule that it correctly captures the idea you have in mind.

Consider the following rule that defines a **sibling** relation between two people:

```
sibling(X,Y) :-
motherOf(X,M), motherOf(Y,M),
fatherOf(X,F), fatherOf(Y,F).
```

This rule says that  $\mathbf{x}$  and  $\mathbf{y}$  are siblings if each has the same mother and the same father.

But the rule is wrong! Why?

no

CS 538 Spring 2008

Note that distinct but equivalent solutions

(like x = dick, y = jane VS.

**x** = jane, **y** = dick) often appear in Prolog solutions. You may sometimes need to "filter out" solutions that are effectively redundant (perhaps by formulating stricter or more precise rules).

CS 538 Spring 2008

# How Prolog Solves Queries

The unique feature of Prolog is that it automatically chooses the facts and rules needed to solve a query.

But how does it make its choice? It starts by trying to solve each goal in a query, left to right (recall goals are connected using "," which is the and operator).

For each goal it tries to *match* a corresponding fact or the head of a corresponding rule.

A fact or head of rule matches a goal if:

- Both use the same predicate.
- Both have the same number of terms following the predicate.

• Each term in the goal and fact or rule head match (are equal), possibly binding a free variable to force a match.

For example, assume we wish to match the following goal:

x(a,B)

This can match the fact

x(a,b).

or the head of the rule

 $\mathbf{x}(\mathbf{Y},\mathbf{Z}) := \mathbf{Y} = \mathbf{Z}.$ 

But **x(a,B)** can't match **y(a,b)** (wrong predicate name) or

**x(b,d)** (first terms don't match) or

**x(a,b,c)** (wrong number of terms).

If we succeed in matching a rule, we have solved the goal in question; we can go on to match any remaining goals.

If we match the head of a rule, we aren't done—we add the body of the rule to the list of goals that must be solved.

Thus if we match the goal **x**(**a**,**B**) with the rule

### $\mathbf{x}(\mathbf{Y},\mathbf{Z}) :- \mathbf{Y} = \mathbf{Z}.$

then we must solve **a=B** which is done by making **B** equal to **a**.

CS 538 Spring 2008

# Example

Let's trace how
| ?- grandMotherOf(tom,GM).
is solved.
Recall that
grandMotherOf(X,GM) : motherOf(X,M),
 motherOf(M,GM).
grandMotherOf(X,GM) :-

```
fatherOf(X,F),
    motherOf(F,GM).
fatherOf(tom,dick).
fatherOf(dick,harry).
fatherOf(jane,harry).
motherOf(tom,judy).
motherOf(dick,mary).
```

# Backtracking

If we reach a point where a goal can't be matched, or the body of a rule can't be matched, we backtrack to the last (most recent) spot where a choice of matching a particular fact or rule was made. We then try to match a different fact or rule. If this fails we go back to the next previous place where a choice was made and try a different match there. We try alternatives until we are able to solve all the goals in our query or until all possible choices have been tried and found to fail. If this happens, we answer "no" the query can't be solved.

As we try to match facts and rules we try them in their order of definition.

CS 538 Spring 2008

409

We try the first grandMotherOf rule first. This forces  $\mathbf{x} = \mathbf{tom}$ . We have to solve motherOf(tom,M), motherOf(M,GM). We now try to solve motherOf(tom,M) This forces  $\mathbf{M} = \mathbf{judy}$ . We then try to solve motherOf(judy,GM) None of the motherOf rules match this goal, so we backtrack. No other **motherOf** rule can solve motherOf(tom,M) so we backtrack again and try the second grandMotherOf rule:

```
grandMotherOf(X,GM) :-
  fatherOf(X,F),
     motherOf(F,GM).
This matches, forcing \mathbf{x} = \mathbf{tom}.
We have to solve
fatherOf(tom,F),
motherOf(F,GM).
We can match the first goal with
fatherOf(tom,dick).
This forces \mathbf{F} = \mathbf{dick}.
We then must solve
motherOf(dick,GM)
which can be matched by
motherOf(dick,mary).
We have matched all our goals, so
we know the query is true, with
GM = mary.
```

### List Processing in Prolog

Prolog has a notation similar to "cons cells" of Lisp and Scheme. The "." functor (predicate name) acts like cons.

Hence . (a,b) in Prolog is essentially the same as (a . b) in Scheme.

Lists in Prolog are formed much the same way as in Scheme and ML:

[] is the empty list

[1,2,3] is an abbreviation for
.(1, .(2, .(3,[])))

just as

CS 538 Spring 2008

(1,2,3) in Scheme is an abbreviation for (cons 1 (cons 2 (cons 3 () )))

CS 538 Spring 2008

413

The notation [H|T] represents a

list with **H** matching the head of the list and **T** matching the rest of the list. Thus  $[1,2,3] \equiv [1| [2,3]] \equiv$  $[1,2| [3]] \equiv [1,2,3| []]$ As in ML, "\_" (underscore) can be used as a wildcard or "don't care"

used as a wildcard or "don't care" symbol in matches.

Given the fact

answers

The query p([\_,\_,X|Y]). answers X = 3, Y = [4]

CS 538 Spring 2008

# List Operations in Prolog

List operations are defined using rules and facts. The definitions are similar to those used in Scheme or ML, but they are *nonprocedural*.

That is, you don't given an execution order. Instead, you give recursive rules and non-recursive "base cases" that characterize the operation you are defining.

Consider append:

append([],L,L).
append([H|T1],L2,[H|T3]) :append(T1,L2,T3).

The first fact says that an empty list (argument 1) appended to any list **L** (argument 2) gives **L** (argument 3) as its answer. The rule in line 2 says that if you take a list that begins with  $\mathbf{H}$  and has  $\mathbf{T1}$  as the rest of the list and append it to a list  $\mathbf{L}$  then the resulting appended list will begin with  $\mathbf{H}$ .

Moreover, the rest of the resulting list, **T3**, is the result of appending **T1** (the rest of the first list) with **L2** (the second input list).

The query

| ?- append([1],[2,3],[1,2,3]).
answers

Yes

CS 538 Spring 2008

because with H=1, T1=[], L2=[2,3] and T3=[2,3] it must be the case that append([],[2,3],[2,3]) is true and fact (1) says that this is so.

CS 538 Spring 2008

417

### **INVERTING INDUTS AND OUTDUTS**

In Prolog the division between "inputs" and "outputs" is intentionally vague. We can exploit this. It is often possible to "invert" a query and ask what *inputs* would compute a given output. Few other languages allow this level of flexibility.

Consider the query

append([1],X,[1,2,3]).

This asks Prolog to find a list **x** such that if we append **[1]** to **x** we will get **[1,2,3]**.

Prolog answers

X = [2,3]

How does it choose this answer?

First Prolog tries to match the query against fact (1) or rule (2). Fact (1) doesn't match (the first arguments differ) so we match rule (2).

This gives us H=1, T1=[], L2=Xand T3 = [2,3].

We next have to solve the body of rule (2) which is

**append([],L2,[2,3]).** Fact (1) matches this, and tells us that **L2=[2,3]=x**, and that's our answer!

# The Member Relation

A common predicate when manipulating lists is a membership test—is a given value a member of a list?

An "obvious" definition is a recursive one similar to what we might program in Scheme or ML: member  $(x, [x|_])$ .

member  $(\mathbf{X}, [-|\mathbf{Y}]) :=$  member  $(\mathbf{X}, \mathbf{Y})$ . This definition states that the first argument,  $\mathbf{X}$ , is a member of the second argument (a list) if  $\mathbf{X}$ matches the head of the list *or* if  $\mathbf{X}$ is (recursively) a member of the rest of the list.

Note that we don't have to "tell" Prolog that **x** *can't* be a member of an empty list—if we don't tell Prolog that something is true, it automatically assumes that it must be false.

Thus saying nothing about membership in an empty list is the same as saying that membership in an empty list is impossible.

Since inputs and outputs in a relation are blurred, we can use **member** in an unexpected way—to iterate through a list of values.

If we want to know if any member of a list **L** satisfies a predicate **p**, we can simply write:

member(X, L), p(X).

CS 538 Spring 2008

421

CS 538 Spring 2008

There is no explicit iteration or searching. We simply ask Prolog to find an  $\mathbf{x}$  such that **member**( $\mathbf{X}$ ,  $\mathbf{L}$ ) is true ( $\mathbf{x}$  is in  $\mathbf{L}$ ) and  $\mathbf{p}$ ( $\mathbf{x}$ ) is true. Backtracking will find the "right" value for  $\mathbf{x}$  (if any such  $\mathbf{x}$  exists). This is sometimes called the "guess and verify" technique. Thus we can query **member**( $\mathbf{X}$ , [ $\mathbf{3}$ ,  $-\mathbf{3}$ ,  $\mathbf{0}$ ,  $\mathbf{10}$ ,  $-\mathbf{10}$ ]), ( $\mathbf{x} > \mathbf{0}$ ). This asks for an  $\mathbf{x}$  in the list [ $\mathbf{3}$ ,  $-\mathbf{3}$ ,  $\mathbf{0}$ ,  $\mathbf{10}$ ,  $-\mathbf{10}$ ] which is greater than  $\mathbf{0}$ .

Prolog answers

x = 3;

X = 10;

Note too that our "obvious" definition of member is not the only one possible.

An alternative definition (which is far less obvious) is

member(X,L) :append(\_,[X|\_],L).

This definition says  $\mathbf{x}$  is a member of  $\mathbf{L}$  if I can take some list (whose value I don't care about) and append it to a list that begins with  $\mathbf{x}$  (and which ends with values I don't care about) and get a list equal to  $\mathbf{L}$ .

Said more clearly,  $\mathbf{x}$  is a member of  $\mathbf{L}$  if  $\mathbf{x}$  is anywhere in the "middle" of  $\mathbf{L}$ .

Prolog solves a query involving **member** by partitioning the list  $\mathbf{L}$  in *all possible ways*, and checking to see if  $\mathbf{x}$  ever is the head of the

# Sorting Algorithms

Sorting algorithms are good examples of Prolog's definitional capabilities. In a Prolog definition the "logic" of a sorting algorithm is apparent, stripped of the cumbersome details of data structures and control structures that dominate algorithms in other programming languages.

Consider the simplest possible sort imaginable, which we'll call the "naive sort."

At the simplest level a sorting of a list **L** requires just two things:

- The sorting is a permutation (a reordering) of the values in **L**.
- The values are "in order" (ascending or descending).

We can implement this concept of a sort directly in Prolog. We

- (a) permute an input list
- (b) check if it is in sorted order
- (c) repeat (a) & (b) until a sorting is found.

### PERMUTATIONS

CS 538 Spring 2008

Let's first look at how permutations are defined in Prolog. In most languages generating permutations is nontrivial—you need data structures to store the permutations you are generating and control structures to visit all permutations in some order.

In Prolog, permutations are defined quite concisely, though with a bit of subtlety:

**perm(X,Y)** will be true if list **Y** is a permutation of list **X**.

Only two definitions are needed:

perm([],[]).

perm(L,[H|T]) :append(V,[H|U],L),
append(V,U,W), perm(W,T).

Let's see perm in action: | ?- perm([1,2,3],X). X = [1, 2, 3];X = [1, 3, 2];X = [2, 1, 3];X = [2,3,1];X = [3, 1, 2];X = [3, 2, 1];no We'll trace how the first few answers are computed. Note though that *all* permutations are generated, and with no apparent data structures or control structures. We start with L=[1,2,3] and X = [H|T].We first solve

append(V,[H|U],L), which

CS 538 Spring 2008

simplifies to

W = [2, 3].

append(V,[H|U],[1,2,3]).

One solution to this goal is

V = [], H = 1, U = [2,3]

The only solution for this is

Finally, we solve perm(W,T),

One solution to this is T = [2, 3].

This gives us our first solution:

To get our next solution we

*backtrack*. Where is the most

recent place we made a choice of

which simplifies to

which simplifies to

perm([2,3],T).

[H|T] = [1, 2, 3].

how to solve a goal?

append([],[2,3],W).

We next solve append (V, U, W)

429

CS 538 Spring 2008

It was at perm([2,3],T). We
chose T=[2,3], but T=[3,2] is
another solution. Using this
solution, we get out next answer
[H|T]=[1,3,2].

Let's try one more. We backtrack again. No more solutions are possible for perm([2,3],T), so we backtrack to an earlier choice point.

At append(V, [H|U], [1,2,3]) another solution is

V=[1], H = 2, U = [3]

Using this binding, we solve **append(V,U,W)** which simplifies to **append([1],[3],W)**. The solution to this must be **W=[1,3]**.

We then solve perm(W,T) which simplifies to perm([1,3],T). One solution to this is T=[1,3]. This

431
```
makes our third solution for [# | T] = [2,1,3]. 
 Tou can check out the other bindings that lead to the last three solutions.
```

# **A PERMUTATION SORT**

Now that we know how to generate permutations, the definition of a permutation sort is almost trivial.

We define an **inOrder** relation that characterizes our notion of when a list is properly sorted:

inOrder([]).

inOrder([\_]).

inOrder([A,B|T]) :-

A =< B, inOrder([B|T]). These definitions state that a null list, and a list with only one element are always in sorted order. Longer lists are in order if the first two elements are in proper order. (A=<B) checks this and then the rest of the list,

CS 538 Spring 2008

433

excluding the first element, is checked. Now our naive permutation sort is only one line long: naiveSort(L1,L2) :perm(L1,L2), inOrder(L2). And the definition works too! | ?naiveSort([1,2,3],[3,2,1]). no ?- naiveSort([3,2,1],L). L = [1, 2, 3];no | ?naiveSort([7,3,88,2,1,6,77, -23,5],L). L = [-23, 1, 2, 3, 5, 6, 7, 77, 88]

Though this sort works, it is hopelessly inefficient—it repeatedly "shuffles" the input until it happens to find an ordering that is sorted. The process is largely undirected. We don't "aim" toward a correct ordering, but just search until we get lucky.

# A Bubble Sort

Perhaps the best known sorting technique is the interchange or "bubble" sort. The idea is simple. We examine a list of values, looking for a pair of adjacent values that are "out of order." If we find such a pair, we swap the two values (placing them in correct order). Otherwise, the whole list must be in sorted order and we are done.

In conventional languages we need a lot of code to search for out-of-order pairs, and to systematically reorder them. In Prolog, the whole sort may be defined in a few lines:

CS 538 Spring 2008

bubbleSort(L,L) :- inOrder(L).

bubbleSort(L1,L2) :append(X,[A,B|Y],L1), A > B,
append(X,[B,A|Y],T),
bubbleSort(T,L2).

The first line says that if **L** is already in sorted order, we are done.

The second line is a bit more complex. It defines what it means for a list L2 to be a sorting for list L1, using our insight that we should swap out-of-order neighbors. We first partition list L1 into two lists, X and [A,B|Y]. This "exposes" two adjacent values in L, A and B. Next we verify that A and B are out-oforder (A>B). Next, in append(X, [B,A|Y],T), we determine that list T is just our

CS 538 Spring 2008

437

input **L**, with **A** and **B** swapped into **B** followed by **A**. Finally, we verify that

**bubbleSort** (**T**, **L2**) holds. That is, **T** may be bubble-sorted into **L2**.

This approach is rather more directed than our permutation sort—we look for an out-of-order pair of values, swap them, and then sort the "improved" list. Eventually there will be no more out-of-order pairs, the list will be in sorted order, and we will be done.

#### **Merge Sort**

Another popular sort in the "merge sort" that we have already seen in Scheme and ML. The idea here is to first split a list of length L into two sublists of length L/2. Each of these two lists is recursively sorted. Finally, the two sorted sublists are merged together to form a complete sorted list.

The bubble sort can take time proportional to  $n^2$  to sort n elements (as many as  $n^2/2$  swaps may be needed). The merge sort does better—it takes time proportional to n log<sub>2</sub> n to sort n elements (a list of size n can only be split in half log<sub>2</sub> n times).

439

We also need rules that characterize how to merge two sorted sublists into a complete sorted list:

merge([],L,L).
merge(L,[],L).
merge([A|T1],[B|T2],[A|L2]) : A =< B, merge(T1,[B|T2],L2).
merge([A|T1],[B|T2],[B|L2]) : A > B, merge([A|T1],T2,L2).

The first 2 lines handle merging null lists. The third line handles the case where the head of the first sublist is  $\leq$  the head of the second sublist; the final rule handles the case where the head of the second sublist is smaller.

CS 538 Spring 2008

With the above definitions, a merge sort requires only three lines:

```
mergeSort([],[]).
```

```
mergeSort([A],[A]).
```

```
mergeSort(L1,L2) :-
split(L1,P1,P2),
mergeSort(P1,S1),
mergeSort(P2,S2),
merge(S1,S2,L2).
```

The first two lines handle the trivial cases of lists of length 0 or 1. The last line contains the full "logic" of a merge sort: split the input list, **L** into two half-sized lists **P1** and **P2**. Then merge sort **P1** into **S1** and **P2** into **S2**. Finally, merge **S1** and **S2** into a sorted list **L2**. That's it!

### **Quick Sort**

The merge sort partitions its input list rather blindly, alternating values between the two lists. What if we partitioned the input list based on *values* rather than positions?

The *quick sort* does this. It selects a "pivot" value (the head of the input list) and divides the input into two sublists based on whether the values in the list are less than the pivot or greater than or equal to the pivot. Next the two sublists are recursively sorted. But now, after sorting, *no merge* phase is needed. Rather, the two sorted sublists can simply be appended, since we know all values in the first list are less than all values in the second list.

443

We need a Prolog relation that characterizes how we will do our partitioning. We we define **partition(E,L1,L2,L3)** to be true if **L1** can be partitioned into **L2** and **L3** using **E** as the pivot element. The necessary rules are:

partition(E,[],[],[]).
partition(E,[A|T1],[A|T2],L3) : A<E, partition(E,T1,T2,L3).
partition(E,[A|T1],L2,[A|T3]) : A>=E, partition(E,T1,L2,T3)

The first line defines a trivial partition of a null list. The second line handles the case in which the first element of the list to be partitioned is less than the pivot, while the final line handles the case in which the list head is greater than or equal to the pivot.

CS 538 Spring 2008

With our notion of partitioning defined, the quicksort itself requires only 2 lines:

```
qsort([],[]).
qsort([A|T],L) :-
partition(A,T,L1,L2),
qsort(L1,S1),qsort(L2,S2),
append(S1,[A|S2],L).
```

The first line defines a trivial sort of an empty list.

The second line says to sort a list that begins with **A** and ends with list **T**, we partition **T** into sublists **L1** and **L2**, based on **A**. Then we recursively quick sort **L1** into **S1** and **L2** into **S2**. Finally we append **S1** to  $[\mathbf{A} | \mathbf{S2}]$ (**A** must be > all values in **S1** and **A** must be  $\leq$  all values in **S2**). The result is **L**, a sorting of  $[\mathbf{A} | \mathbf{T}]$ .

CS 538 Spring 2008

445

### ARITHMETIC IN PROLOG

The = predicate can be used to test bound variables for equality (actually, identity).

If one or both of ='s arguments are free variables, = forces a binding or an equality constraint.

```
Thus
```

```
| ?- 1=2.
no
| ?- X=2.
X = 2
| ?- Y=X.
Y = X = _10751
| ?- X=Y, X=joe.
X = Y = joe
```

# ARITHMETIC TERMS ARE SYMBOLIC

Evaluation of an arithmetic term into a numeric value must be *forced*.

That is, **1+2** is an infix representation of the relation **+(1,2)**. This term is *not* an integer!

Therefore

```
| ?- 1+2=3.
```

no

To force arithmetic evaluation, we use the infix predicate **is**.

The right-hand side of **is** must be all *ground terms* (literals or variables that are already bound). No *free* (unbound) variables are allowed.

```
Hence
|?- 2 is 1+1.
yes
| ?- X is 3*4.
X = 12
| ?- Y is Z+1.
! Instantiation error in argument
2 of is/2
! goal: _10712 is _10715+1
```

The requirement that the righthand side of an **is** relation be ground is essentially procedural. It exists to avoid having to invert complex equations. Consider,

(0 is (I\*\*N)+(J\*\*N)-K\*\*N)), N>2.

# COUNTING IN PROLOG

Rules that involve counting often use the **is** predicate to evaluate a numeric value.

Consider the relation **len(L,N)** that is true if the length of list **L** is **N**.

```
len([],0).
len([_|T],N) :-
    len(T,M), N is M+1.
| ?- len([1,2,3],X).
X = 3
| ?- len(Y,2).
Y = [_10903,_10905]
The symbols _10903 and _10905
```

are "internal variables" created as needed when a particular value is not forced in a solution.

```
CS 538 Spring 2008
```

449

CS 538 Spring 2008

# DEBUGGING PROLOG

Care is required in developing and testing Prolog programs because the language is untyped; undeclared predicates or relations are simply treated as false.

Thus in a definition like

```
adj([A,B|_]) :- A=B.
adj([_,B|T]) :- adk([B|T]).
| ?- adj([1,2,2]).
no
```

(Some Prolog systems warn when an undefined relation is referenced, but many others don't).

```
Similarly, given
 member(A, [A|_]).
 member(A,[_|T]) :-
  member(A, [T]).
| ?- member(2, [1, 2]).
Infinite recursion! (Why?)
If you're not sure what is going
on, Prolog's trace feature is very
handy.
The command
trace.
turns on tracing. (notrace turns
tracing off).
Hence
?- trace.
ves
[trace]
?- member(2,[1,2]).
```

```
(1) 0 Call: member(2,[1,2]) ?
   (1) 1 Head [1->2]:
member(2,[1,2]) ?
   (1) 1 Head [2]:
member(2,[1,2]) ?
   (2) 1 Call: member(2,[[2]]) ?
   (2) 2 Head [1->2]:
member(2,[[2]]) ?
   (2) 2 Head [2]:
member(2,[[2]]) ?
   (3) 2 Call: member(2,[[]]) ?
   (3) 3 Head [1->2]:
member(2,[[]]) ?
   (3) 3 Head [2]: member(2,[[]])
?
   (4) 3 Call: member(2,[[]]) ?
   (4) 4 Head [1->2]:
member(2,[[]]) ?
   (4) 4 Head [2]: member(2,[[]])
2
   (5) 4 Call: member(2,[[]]) ?
```

### **TERMINATION ISSUES IN PROLOG**

Searching infinite domains (like integers) can lead to nontermination, with Prolog trying every value. Consider odd(1). odd(N) :- odd(M), N is M+2. | ?- odd(X). X = 1 ; X = 3 ; X = 5 ; X = 7

CS 538 Spring 2008

#### A query

| ?- odd(X), X=2.

going into an *infinite* search, generating each and every odd integer and finding none is equal to 2!

The obvious alternative,

odd(2) (which is equivalent to

**x=2, odd(x)**) also does an infinite, but fruitless search. We'll soon learn that Prolog does have a mechanism to "cut off" fruitless searches.

# **Definition Order CAN MATTER**

Ideally, the order of definition of facts and rules should not matter. *But*.

in practice definition order can matter. A good general guideline is to define facts before rules. To see why, consider a very complete database of **motherOf** relations that goes back as far as

motherOf(cain,eve).

Now we define

isMortal(X) : isMortal(Y), motherOf(X,Y).
isMortal(eve).

CS 538 Spring 2008

453

```
These definitions state that the
first woman was mortal, and all
individuals descended from her
are also mortal.
But when we try as trivial a query
as
?- isMortal(eve).
we go into an infinite search!
Why?
Let's trace what Prolog does when
it sees
?- isMortal(eve).
It matches with the first definition
involving isMorta1. which is
isMortal(X) :-
  isMortal(Y), motherOf(X,Y).
It sets x=eve and tries to solve
isMortal(Y), motherOf(eve,Y).
It will then expand isMortal(Y)
into
```

CS 538 Spring 2008

isMortal(Z), motherOf(Y,Z). An infinite expansion ensues. The solution is simple—place the "base case" fact that terminates recursion first. If we use isMortal(eve). isMortal(X) :isMortal(Y), motherOf(X,Y). yes | ?isMortal(eve). yes But now another problem appears! If we ask ?- isMortal(clarkKent). we go into another infinite search! Whv? The problem is that Clark Kent is from the planet Krypton, and

CS 538 Spring 2008

457

hence won't appear in our **motherOf** database. Let's trace the query.

It doesn't match

isMortal(eve).

We next try

```
isMortal(clarkKent) :-
    isMortal(Y),
    motherOf(clarkKent,Y).
```

We try **Y=eve**, but **eve** isn't Clark's mother. So we recurse, getting:

```
isMortal(Z), motherOf(Y,Z),
motherOf(clarkKent,Y).
```

But **eve** isn't Clark's grandmother either! So we keep going further back, trying to find a chain of descendents that leads from **eve** to **clarkKent**. No such chain exists, and there is no limit to how long a chain Prolog will try. There is a solution though! We simply rewrite our recursive definition to be

```
isMortal(X) :-
  motherOf(X,Y),isMortal(Y).
```

This is logically the same, but now we work from the individual **x** back toward **eve**, rather than from **eve** toward **x**. Since we have no **motherOf** relation involving **clarkKent**, we immediately stop our search and answer **no**!

459

### Extra-logical Aspects of Prolog

To make a Prolog program more efficient, or to represent negative information, Prolog needs features that have a procedural flavor. These constructs are called "extra-logical" because they go beyond Prolog's core of logicbased inference.

CS 538 Spring 2008

461

We *can* backtrack to try various solutions to **v**(**B**,**C**).

It is sometimes useful to have several 1's in a rule. This allows us to find a partial solution, lock it in, find a further solution, then lock it in, etc.

For example, in a rule

a(x) - b(x), !, c(x, y), !, d(y).
we first try to satisfy b(x), perhaps trying several facts or rules that define the b relation.
Once we have a solution to b(x), we lock it in, along with the binding for x.

Then we try to satisfy c(x, y), using the fixed binding for x, but perhaps trying several bindings for y until c(x, y) is satisfied.

We then lock in this match using another 1.

### ΤΗΕ Ουτ

The most commonly used extralogical feature of Prolog is the "cut symbol," "!"

A : in a goal, fact or rule "cuts off" backtracking.

In particular, once a **!** is reached (and automatically matched), we may *not backtrack* across it. The rule we've selected and the bindings we've already selected are "locked in" or "frozen."

For example, given

x(A) := y(A,B), z(B), !, v(B,C).once the ! is hit we can't backtrack to resatisfy y(A,B) or z(B) in some other way. We are locked into this rule, with the bindings of A and B already in place.

CS 538 Spring 2008

Finally we check if  $\mathbf{d}(\mathbf{Y})$  can be satisfied with the binding of  $\mathbf{Y}$  already selected and locked in.

CS 538 Spring 2008

CS 538 Spring 2008

### WHEN ARE CUTS NEEDED?

A cut can be useful in improving efficiency, by forcing Prolog to avoid useless or redundant searches.

Consider a query like

member(X,list1),

member (X, list2), isPrime (X). This asks Prolog to find an X that is in list1 and also in list2 and also is prime.

**x** will be bound, in sequence, to each value in **list1**. We then check if **x** is also in **list2**, and then check if **x** is prime.

Assume we find **x=8** is in **list1** and **list2**. **isPrime(8)** fails (of course). We backtrack to **member(X, list2)** and resatisfy it with the same value of **x**.

CS 538 Spring 2008

465

But clearly there is *never* any point in trying to resatisfy **member(X,list2)**. Once we know a value of **x** is in **list2**, we test it using **isPrime(X)**. If it fails, we want to go right back to **member(X,list1)** and get a different **x**.

To create a version of member that never backtracks once it has been satisfied we can use !.

We define

member1(X, [X|\_]) :- !.
member1(X, [\_|Y]) :member1(X,Y).

Our query is now

member(X,list1), member1(X,list2), isPrime(X). (Why isn't member1 used in both terms?)

CS 538 Spring 2008

#### Expressing Negative Information

Sometimes it is useful to state rules about what *can't* be true. This allows us to avoid long and fruitless searches.

**fail** is a goal that always fails. It can be used to represent goals or results that can never be true.

Assume we want to optimize our **grandMotherOf** rules by stating that a male can never be anyone's grandmother (and hence a complete search of all **motherOf** and **fatherOf** relations is useless).

A rule to do this is

grandMotherOf(X,GM) : male(GM), fail.

This rule doesn't do quite what we hope it will!

#### Why?

The standard approach in Prolog is to try other rules if the current rule fails.

Hence we need some way to "cut off" any further backtracking once this negative rule is found to be applicable.

This can be done using

grandMotherOf(X,GM) :male(GM),!, fail.

### Other Extra-Logical Operators

#### assert and retract

These operators allow a Prolog program to add new rules during execution and (perhaps) later remove them. This allows programs to learn as they execute.

#### •findall

Called as findall(x, goal, List) where x is a variable in goal. All possible solutions for x that satisfy goal are found and placed in List.

For example, findall(x, (append(\_,[X|\_],[-1,2,-3,4]),(X<0)), L). L = [-1,-3]

CS 538 Spring 2008

var and nonvar

**var(X)** tests whether **X** is *unbound* (free).

**nonvar(Y)** tests whether **Y** is *bound* (no longer free).

These two operators are useful in tailoring rules to particular combinations of bound and unbound variables. For example,

grandMotherOf(X,GM) :male(GM),!, fail. might backfire if GM is not yet bound. We could set GM to a person for whom male(GM) is true, then fail because we don't

want grandmothers who are male! To remedy this problem. we use the rule only when GM is bound. Our rule becomes

grandMotherOf(X,GM) : nonvar(GM), male(GM),!, fail.

CS 538 Spring 2008

469

### An Example of Extra-Logical Programming

Factorial is a very common example program. It's well known, and easy to code in most languages.

In Prolog the "obvious" solution is:

fact(N,1) := N = < 1.

fact(N,F) :- N > 1, M is N-1,
fact(M,G), F is N\*G.

This definition is certainly correct. It mimics the usual recursive solution.

#### But,

in Prolog "inputs" and "outputs" are less distinct than in most languages.

In fact, we can envision 4 different combinations of inputs

and outputs, based on what is fixed (and thus an input) and what is free (and hence is to be computed):

1. **n** and **F** are both ground (fixed). We simply must decide if F=N!

2. **N** is ground and **F** is free. This is how **fact** is usually used. We must compute an **F** such that F=N!

3. **F** is fixed and **N** is free. This is an uncommon usage. We must find an **N** such that F=N!, or determine that no such **N** is possible.

4. Both **n** and **F** are free. We generate, in sequence, pairs of **n** and **F** values such that F=N!

```
Our solution works for
combinations 1 and 2 (where \mathbf{N} is
fixed), but not combinations 3
and 4. (The problem is that \mathbf{N} = <
1 \text{ and } \mathbf{N} > 1 \text{ can't be satisfied}
when n is free).
We'll need to use nonvar and ! to
form a solution that works for all
4 combinations of inputs.
We first handle the case where N
is around:
fact(1,1).
fact(N,1) := nonvar(N), N = < 1, !.
fact(N,F) := nonvar(N), N > 1, !,
M is N-1, fact(M,G), F is N*G, !.
The first rule handles the base
case of N=1.
The second rule handles the case
of N<1.
```

CS 538 Spring 2008

473

The third rule handles the case of  $\mathbf{N} > 1$ . The value of  $\mathbf{F}$  is computed recursively. The first ! in each of these rules forces that rule to be the *only one* used for the values of  $\mathbf{N}$  that match. Moreover, the second ! in the third rule states that after  $\mathbf{F}$  is computed, further backtracking is useless; there is only one  $\mathbf{F}$  value for any given  $\mathbf{N}$  value. To handle the case where  $\mathbf{F}$  is bound and  $\mathbf{N}$  is free, we use

fact(N,F) :- nonvar(F), !,
fact(M,G), N is M+1, F2 is N\*G,
F =< F2, !, F=F2.</pre>

In this rule we generate  $\mathbf{N}$ ,  $\mathbf{F2}$ pairs until  $\mathbf{F2} \ge \mathbf{F}$ . Then we check if  $\mathbf{F=F2}$ . If this is so, we have the  $\mathbf{N}$  we want. Otherwise, no such  $\mathbf{N}$  can exist and we fail (and answer no).

CS 538 Spring 2008<sup>®</sup>

For the case where both  $\mathbf{N}$  and  $\mathbf{F}$  are free we use:

fact(N,F) :- fact(M,G), N is M+1, F is N\*G.

This systematically generates **N**, **F** pairs, starting with **N=2**, **F=2** and then recursively building successor values (**N=3**, **F=6**, then **N=4**, **F=24**, etc.)

# PARALLELISM IN PROLOG

One reason that Prolog is of interest to computer scientists is that its search mechanism lends itself to *parallel evaluation*.

In fact, it supports two different kinds of parallelism:

- AND Parallelism
- OR Parallelism

CS 538 Spring 2008

477

# **OR PARALLELISM**

When we match a goal we almost always have a choice of several rules or facts that may be applicable. Rather than try them in sequence, we can try several matches of different facts or rules in parallel. This is "or parallelism." Thus given

```
a(X) := b(X).
```

```
a(Y) := c(Y).
```

when we try to solve

```
a(10).
```

we can simultaneously check both **b(10)** and **c(10)**.

```
Recall our definition of
member(X,L) :-
 append(P, [X|S], L).
where append is defined as
append([],L,L).
append([X|L1],L2,[X|L3]) :-
 append(L1,L2,L3).
Assume we have the query
? member(2,[1,2,3]).
This immediately simplifies to
append(P,[2|S],[1,2,3]).
Now there are two append
definitions we can try in parallel:
(1) match append (P, [2|S], [1,2,3])
with append([],L,L). This
requires that [2|s] = [1, 2, 3],
which must fail.
(2) match
append(P,[2|S],[1,2,3]) With
append([X|L1], L2, [X, L3]).
```

This requires that P=[x|L1], [2|S]=L2, [1,2,3]=[X,L3].Simplifying, we require that **x=1**, P = [1|L1], L3 = [2,3].Moreover we must solve append(L1,L2,L3) which simplifies to append(L1,[2|S],[2,3]). We can match this call to **append** in two different ways, so or parallelism can be used again. When we try matching append(L1, [2|S], [2,3]) against append([],L,L) We get [2|s] = [2,3], which is satisfiable if **s** is bound to **[31**. We therefore signal back that the query is true.

CS 538 Spring 2008

481

tests. If it is, we'll ask **member(X, list1)** to find a new binding for **x**. If we wish, this next binding can be generated *speculatively*, while the current value of  $\mathbf{x}$  is being tested. In this way if the current value of  $\mathbf{x}$  is rejected, we'll have a new value ready to try (or know that no other binding of  $\mathbf{x}$  is possible). If the current value of  $\mathbf{x}$  is accepted, the extra speculative work we did is ignored. It wasn't needed, but was useful insurance in case further **x** bindings were needed.

# **Speculative Parallelism**

Prolog also lends itself nicely to *speculative* parallelism. In this form of parallelism, we "guess" or speculate that some computation *may* be needed in the future and start it early. This speculative computation can often be done in parallel with the main (non-speculative) computation.

Recall our example of

member(X,list1),
 member1(X,list2), isPrime(X).

After member(X,list1) has generated a preliminary solution for x, it is tested (perhaps in parallel) by member1(X,list2) and isPrime(X).

But this value of **x** may be rejected by one or both of these

CS 538 Spring 2008

# **Reading Assignment**

 Python Tutorial (linked from class web page)

483

### Рутном

A modern and innovative scripting languages is *Python*, developed by Guido van Rossum in the mid-90s. Python is named after the BBC "Monty Python" television series.

Python blends the expressive power and flexibility of earlier scripting languages with the power of object-oriented programming languages.

It offers a lot to programmers:

- An interactive development mode as well as an executable "batch" mode for completed programs.
- Very reasonable execution speed. Like Java, Python programs are compiled. Also like Java, the compiled code is in an intermediate

CS 538 Spring 2008

485

language for which an interpreter is written. Like Java this insulates Python from many of the vagaries of the actual machines on which it runs, giving it portability of an equivalent level to that of Java. Unlike Java, Python retains the interactivity for which interpreters are highly prized.

- Python programs require no compilation or linking. Nevertheless, the semi-compiled Python program still runs much faster than its traditionally interpreted rivals such as the shells, *awk* and *perl*.
- Python is freely available on almost all platforms and operating systems (Unix, Linux, Windows, MacOs, etc.)

CS 538 Spring 2008

- Python is completely *object oriented*. It comes with a full set of objected oriented features.
- Python presents a first class object model with first class functions and multiple inheritance. Also included are classes, modules, exceptions and late (run-time) binding.
- Python allows a clean and open program layout. Python code is less cluttered with the syntactic "noise" of declarations and scope definitions. Scope in a Python program is defined by the *indentation* of the code in question. Python thus breaks with current language designs in that white space has now once again acquired significance.

- Like Java, Python offers automated memory management through runtime reference counting and garbage collection of unreferenced objects.
- Python can be embedded in other products and programs as a control language.
- Python's interface is well exposed and is reasonably small and simple.
- Python's license is truly public. Python programs can be used or sold without copyright restrictions.
- Python is extendable. You can dynamically load compiled Python, Python source, or even dynamically load new machine (object) code to provide new features and new facilities.

487

- Python allows low-level access to its interpreter. It exposes its internal plumbing to a significant degree to allow programs to make use of the way the plumbing works.
- Python has a rich set of external library services available. This includes, network services, a GUI API (based on tcl/Tk), Web support for the generation of HTML and the CGI interfaces, direct access to databases, etc.

Using Python

Python may be used in either interactive or batch mode.

In interactive mode you start up the Python interpreter and enter executable statements. Just naming a variable (a trivial expression) evaluates it and echoes its value.

For example (>>> is the Python interactive prompt):

>>> 1
1
>>> a=1
>>> a
1
>>> b=2.5
>>> b
2.5

CS 538 Spring 2008

489

>>> a+b 3.5 >>> print a+b 3.5

You can also incorporate Python statements into a file and execute them in batch mode. One way to do this is to enter the command

#### python file.py

where **file.py** contains the Python code you want executed. Be careful though; in batch mode you must use a **print** (or some other output statement) to force output to be printed. Thus

- 1
- a=1
- a

b=2.5

#### b

CS 538 Spring 2008

a+b

#### print a+b

when run in batch mode prints only **3.5** (the output of the **print** statement).

You can also run Python programs as Unix shell scripts by adding the line

**#! /usr/bin/env python** to the head of your Python file.

(Since **#** begins Python comments, you can also feed the same augmented file directly to the Python interpreter)

#### Identifiers and Reserved Words

Identifiers look much the same as in most programming languages. They are composed of letters, digits and underscores. Identifiers must begin with a letter or underscore. Case is significant. As in C and C++, identifiers that begin with an underscore often have special meaning.

Python contains a fairly typical set of reserved words:

and	del	for	is	raise
assert	elif	from	lambda	return
break	else	global	not	try
class	except	if	or	while
continue	exec	import	pass	
def	finally	in	print	

Compound statements, like **if** statements and **while** loops, *can* span multiple lines, but individual statements within an **if** or **while** (if they are primitive) must appear

#### Why this restriction?

With it, ;'s are mostly

A ; at the end of a statement is legal but usually unnecessary, as the end-of-line forces the

You can use a ; to squeeze more than one statement onto a line, if

# **NUMERIC TYPES**

# There are four numeric types:

- 1. Integers, represented as a 32 bit (or longer) quantity. Digits sequences (possibly) signed are integer literals:
  - -123 +456 1
- 2. Long integers, of unlimited precision. An integer literal followed by an 1 or L is a long integer literal: 1234567890000000000000
- 3. Floating point values, represented as a 64 bit floating point number. Literals are of fixed decimal or exponential form: 123.456 1e10 6.0231023

4. Complex numbers, represented as a pair of floating point numbers. In complex literals j or j is used to denote the imaginary part of the complex value:
1.0+2.0j -22.1j 10e10J+20.0
There is no character type. A literal like 'a' or "c" denotes a string of length one.
There is no boolean type. A zero numeric value (any form), or None (the equivalent of void) or an

empty string, list, tuple or dictionary is treated as false; other values are treated as true. Hence

### "abc" and "def"

is treated as true in an if, since both strings are non-empty.

CS 538 Spring 2008

### **ARITHMETIC OPERATORS**

#### Op Description

- **\*\*** Exponentiation
- + Unary plus
- Unary minus
- Bit-wise complement (int or long only)
- \* Multiplication
- / Division
- % Remainder
- + Binary plus
- Binary minus
- << Bit-wise left shift (int or long only)
- >> Bit-wise right shift (int or long only)
- & Bit-wise and (int or long only)
- Bit-wise or (int or long only)
- Bit-wise Xor (int or long only)

CS 538 Spring 2008

497

- < Less than
- > Greater than
- >= Greater than or equal
- <= Less than or equal
- == Equal
- != Not equal
- and Boolean and
- or Boolean or
- **not** Boolean not

# **Operator Precedence Levels**

Listed from lowest to highest:

or	Boolean OR
and	Boolean AND
not	Boolean NOT
<, <=, >,	, >=, <>, !=, == Comparisons
	Bitwise OR
*	Bitwise XOR
&	Bitwise AND
<<, >>	Shifts
+, -	Addition and subtraction
*,/,%	Multiplication, division, remainder
* *	Exponentiation
+, -	Positive, negative (unary)
~	Bitwise not

Arithmetic Operator Use
Arithmetic operators may be used with any arithmetic type, with conversions automatically applied. Bit-wise operations are restricted to integers and long integers. The result type is determined by the "generality" of the operands. (Long is more general than int, float is more general than both int and long, complex is the most general numeric type). Thus >>> 1+2 3 >>> 1+111L 112L >>> 1+1.1 2.1 >>> 1+2.0j

#### (1+2j)

Unlike almost all other programming languages, relational operators may be "chained" (as in standard mathematics).

Therefore

CS 538 Spring 2008

501

a > b > c

means (a > b) and (b > c)

CS 538 Spring 2008

Assignment Statements

In Python assignment is a statement *not* an expression. Thus

a+(b=2)

is illegal.

Chained assignments are allowed:

a = b = 3

Since Python is dynamically typed, the type (and value) associated with an identifier can change because of an assignment:

```
>>> a = 0
>>> print a
0
>>> a = a + 0L
>>> print a
```

```
OL
>>> a = a + 0.0
>>> print a
0.0
>>> a = a + 0.0J
>>> print a
0j
```

CS 538 Spring 2008

# The if Statement

The full form of the **if** statement is **if** expression:

```
statement(s)
elif expression:
```

```
statement(s)
```

```
•••
```

```
else:
```

```
statement(s)
```

Note those pesky :'s at the end of the **if**, **elif** and **else** lines. The expressions following the **if** and optional **elif** lines are evaluated until one evaluates to true. Then the following statement(s), delimited by indentation, are executed. If no expression evaluates to true, the statements following the **else** are executed.

```
Use of else and elif are
optional; a "bare" if may be used.
If any of the lists of statements is
to be null, use pass to indicate
that nothing is to be done.
For example
if a>0:
    b=1
elif a < 0:
    pass
else:
    b=0
This if sets b to 1 if a is > 0; it
sets b to 0 if a == 0, and does
nothing if a < 0.
```

### BREAK, CONTINUE AND ELSE IN Loops

Like C, C++ and Java, Python allows use of **break** within a loop to force loop termination. For example,

>>> a=1 >>> while a < 10: if a+a == a\*\*2: . . . break . . . else: . . . a=a+1. . . . . . >>> print a 2

CS 538 Spring 2008

509

CS 538 Spring 2008

A **continue** may be used to force the next loop iteration: >>> a=1 >>> while a < 100: a=a+1 . . . if a%2==0: . . . continue . . . a=3\*a • • • . . . >>> print a 105

Python also allows you to add an else clause to a while (or for) loop.

The syntax is

while expression:

body

else:

statement(s)

The **else** statements are executed when the termination condition becomes false, but not when the loop is terminated with a **break**. As a result, you can readily program "search loops" that need to handle the special case of search failure:

### **SEQUENCE TYPES**

Python includes three *sequence types:* strings, tuples and lists. All sequence types may be indexed, using a very general indexing system.

Strings are sequences of characters; tuples and lists may contain any type or combination of types (like Scheme lists).

Strings and tuples are *immutable* (their components may not be changed). Lists *are* mutable, and be updated, much like arrays.

Strings may be delimited by either a single quote (') or a double quote (") or even a triple quote (''' or """). A given string must start and stop with the same delimiter. Triply quoted strings may span multiple lines. There is

CS 538 Spring 2008

no character type or value; characters are simply strings of length 1. Legal strings include

'abc' "xyz" '''It's OK!'''

Lists are delimited by "[" and "]". Empty (or null lists) are allowed. Valid list literals include

[1,2,3] ["one",1] [['a'],['b'],['c']] [] Tuples are a sequence of values separated by commas. A tuple may be enclosed within parentheses, but this isn't required. A empty tuple is (). A singleton tuple ends with a

comma (to distinguish it from a simple scalar value).

Thus (1,) or just 1, is a valid tuple of length one.

# Indexing Sequence Types

Python provides a very general and powerful indexing mechanism. An index is enclosed in brackets, just like a subscript in C or Java. Indexing starts at 0.

Thus we may have

```
>>> 'abcde'[2]
'c'
>>> [1,2,3,4,5][1]
2
>>> (1.1,2.2,3.3)[0]
1.1
Using an index that's too big
raises an IndexError exception:
>>> 'abc'[3]
IndexError: string index out of
range
```

515

```
Unlike most languages, you can
use negative index values; these
simply index from the right:
>>> 'abc'[-1]
'c'
>>> [5,4,3,2,1][-2]
>>> (1,2,3,4)[-4]
1
You may also access a slice of a
sequence value by supplying a
range of index values. The
notation is
 data[i:j]
which selects the values in data
that are >=i and < j. Thus
>>> 'abcde'[1:2]
'b'
>>> 'abcde'[0:3]
'abc'
```

```
>>> 'abcde'[2:2]
You may omit a lower or upper
bound on a range. A missing
lower bound defaults to 0 and a
missing upper bound defaults to
the maximum legal index. For
example.
>>> [1,2,3,4,5][2:]
[3, 4, 5]
>>> [1,2,3,4,5][:3]
[1, 2, 3]
An upper bound that's too large in
a range is interpreted as the
maximum legal index:
>>> 'abcdef'[3:100]
'def'
```

You may use negative values in ranges too—they're interpreted as being relative to the right end of the sequence:

```
CS 538 Spring 2008
```

517

>>> 'abcde'[0:-2] 'abc' >>> 'abcdefg'[-5:-2] 'cde' >>> 'abcde'[-3:] 'cde' >>> 'abcde'[:-1] 'abcd' Since arrays may be assigned to, you may assign a slice to change several values at once: >>> a=[1,2,3,4] >>> a[0:2]=[-1,-2] >>> a [-1, -2, 3, 4]>>> a[2:]=[33,44] >>> a [-1, -2, 33, 44]

The length of the value assigned to a slice *need not* be the same size as the slice itself, so you can shrink or expand a list by assigning slices: >>> a=[1,2,3,4,5]

```
>>> a[2:3]=[3.1,3.2]
>>> a
[1, 2, 3.1, 3.2, 4, 5]
>>> a[4:]=[]
>>> a
[1, 2, 3.1, 3.2]
>>> a[:0]=[-3,-2,-1]
>>> a
[-3, -2, -1, 1, 2, 3.1, 3.2]
```

CS 538 Spring 2008

# Other Operations on Sequences

Besides indexing and slicing, a number of other useful operations are provided for sequence types (strings, lists and tuples).

#### These include:

+ (catenation):
>>> [1,2,3]+[4,5,6]
[1, 2, 3, 4, 5, 6]
>>> (1,2,3)+(4,5)
(1, 2, 3, 4, 5)
>>> (1,2,3)+[4,5]
TypeError: illegal argument
type for built-in operation
>>> "abc"+"def"
'abcdef'

CS 538 Spring 2008

521

### **Operations on Lists**

As well as the operations available for all sequence types (including lists), there are many other useful operations available for lists. These include:

• **count** (Count occurrences of an item in a list):

```
>>> [1,2,3,3,21].count(3)
2
```

• **index** (Find first occurrence of an item in a list):

```
>>> [1,2,3,3,21].index(3)
2
>>> [1,2,2,2,21].index(17
```

```
>>> [1,2,3,3,21].index(17)
ValueError: list.index(x): x
not in list
```

• **remove** (Find and remove an item from a list): >>> a=[1,2,3,4,5] >>> a.remove(4) >>> a [1, 2, 3, 5] >>> a.remove(17) ValueError: list.remove(x): x not in list • pop (Fetch and remove i-th element of a list): >>> a=[1,2,3,4,5] >>> a.pop(3) 4 >>> a [1, 2, 3, 5] >>> a.pop() 5 >>> a [1, 2, 3]

CS 538 Spring 2008

#### DICTIONARIES Python also provides a *dictionary* type (sometimes called an associative array). In a dictionary you can use a number (including a float or complex), string or tuple as an index. In fact any *immutable* type can be an index (this excludes lists and dictionaries). An empty dictionary is denoted **{ }**. A non-empty dictionary may be written as { key1:value1, key2:value2, ... } For example, c={ 'bmw':650, 'lexus':'LS 460', 'mercedes':'S 550'}

CS 538 Spring 2008

525

You can use a dictionary much like an array, indexing it using keys, and updating it by assigning a new value to a key: >>> c['bmw'] 650 >>> c['bmw']='M6' >>> c['honda']='accord' You can delete a value using del: >>> del c['honda'] >>> c['honda'] KeyError: honda

You can also check to see if a given key is valid, and also list all keys, values, or key-value pairs in use:

```
>>> c.has_key('edsel')
0
>>> c.keys()
['bmw', 'mercedes', 'lexus']
>>> c.values()
['M6', 'S 550', 'LS 460']
>>> c.items()
[('bmw', 'M6'), ('mercedes',
   'S 550'), ('lexus', 'LS 460')]
```

CS 538 Spring 2008

- ·	
For Loops	
In Python's <b>for</b> loops, you don't explicitly control the steps of an iteration. Instead, you provide a sequence type (a string, list or sequence), and Python <i>automatically</i> steps through the values.	
Like a <b>while</b> loop, you must end the for loop header with a " <b>:</b> " and the body is delimited using indentation. For example,	
>>> for c in 'abc':	
print c	
a	
b	
C	
CS 538 Spring 2008	52

```
The range function, which
creates a list of values in a fixed
range is useful in for loops:
>>> a=[5,2,1,4]
>>> for i in range(0,len(a)):
... a[i]=2*a[i]
...
>>> print a
[10, 4, 2, 8]
```

CS 538 Spring 2008

You can use an **else** with **for** loops too. Once the values in the specified sequence are exhausted, the **else** is executed unless the **for** is exited using a **break**. For example, **for i in a:** 

```
if i < 0:
    print 'Neg val:',i
    break
-</pre>
```

```
else:
```

```
print 'No neg vals'
```

#### SETS

```
Lists are often used to represent
sets, and Python allows a list (or
string or tuple) to be converted to
a set using the set function:
>>> set([1,2,3,1])
set([1, 2, 3])
>>> set("abac")
set(['a', 'c', 'b'])
>>> set((1,2,3,2,1))
set([1, 2, 3])
Sets (of course) disallow duplicate
elements. They are unordered
(and thus can't be indexed), but
they can be iterated through
using a for:
>>> for v in set([1,1,2,2,3,4,2,1]):
      print v,
. . .
1 2 3 4
```

```
The usual set operators are
provided:
Union (|),
Intersection (&).
Difference (-)
and Symmetric Difference
(*, select members in either but
 not both operands)
>>> set([1,2,3]) | set([3,4,5])
set([1, 2, 3, 4, 5])
>>> set([1,2,3]) & set([3,4,5])
set([3])
>>> set([1,2,3]) - set([3,4,5])
set([1, 2])
>>> set([1,2,3]) ^ set([3,4,5])
set([1, 2, 4, 5])
```

### **List Comprehensions**

Python provides an elegant mechanism for building a list by embedding a for within list brackets. This a termed a *List Comprehension.* 

The general form is an expression, followed by a for to generate values, optionally followed by ifs (to select or reject values) of additional fors.

In essence this is a procedural version of a map, without the need to actually provide a function to be mapped.

To begin with a simple example, >>> [2\*i for i in [1,2,3]] [2, 4, 6]

CS 538 Spring 2008

533

This is the same as mapping the doubling function on the list [1,2,3], but without an explicit function. With an if to filter values, we might have:

>>> [2\*i for i in [3,2,1,0,-1] if i != 0]
[6, 4, 2, -2]

We can also (in effect) nest **for**'s: [(x,y) for x in [1,2,3] for y in [-1,0] ]

```
[(1, -1), (1, 0), (2, -1), (2, 0), (3, -1), (3, 0)]
```

### **FUNCTION DEFINITIONS**

CS 538 Spring 2008

Function definitions are of the form

```
def name(args):
    body
```

The symbol **def** tells Python that a function is to be defined. The function is called **name** and **args** is a tuple defining the names of the function's arguments. The **body** of the function is delimited using indentation. For example,

```
def fact(n):
    if n<=1:
        return 1
    else:
        return n*fact(n-1)
>>> fact(5)
120
>>> fact(20L)
```

CS 538 Spring 2008

```
2432902008176640000L
                                                          Arguments may be given a default
                                                          value, making them optional in a
    >>> fact(2.5)
                                                          call. Optional parameters must
    3.75
                                                          follow required parameters in
    >>> fact(2+1J)
                                                          definitions. For example,
    (1+3j)
                                                           >>> def expo(val,exp=2):
    Scalar parameters are passed by
                                                                return val**exp
                                                          . . .
    value; mutable objects are
    allocated in the heap and hence
                                                          . . .
    are passed (in effect) by reference:
                                                          >>> expo(3,3)
    >>> def asg(ar):
                                                          27
                                                          \rightarrow expo(3)
           a[1]=0
    . . .
                                                          9
           print ar
     . . .
                                                          >>> expo()
     . . .
                                                          TypeError: not enough arguments;
    >>> a=[1,2,3,4.5]
                                                          expected 1, got 0
    >>> asg(a)
    [1, 0, 3, 4.5]
CS 538 Spring 2008
                                                     CS 538 Spring 2008
                                           537
```

A *variable* number of arguments is allowed; you prefix the last formal parameter with a \*; this parameter is bound to a *tuple* containing all the actual parameters provided by the caller: >>> def sum(\*args): sum=0 . . . for i in args: . . .

```
sum=sum+i
. . .
      return sum
• • •
>>> sum(1,2,3)
6
>>> sum(2)
2
>>> sum()
```

```
You may also use the name of
formal parameters in a call,
making the order of parameters
less important:
```

```
>>> def cat(left="[",body="",
    right="]"):
. . .
```

```
return left+body+right
```

```
. . .
>>> cat(body='xyz');
'[xyz]'
>>> cat(body='hi there!'
   ,left='--[')
```

```
'--[hi there!]'
```

# Scoping Rules in Functions

Each function body has its own local namespace during execution. An identifier is resolved (if possible) in the local namespace, then (if necessary) in the global namespace.

#### Thus

```
>>> def f():
... a=11
... return a+b
...
>>> b=2;f()
13
>>> a=22;f()
13
>>> b=33;f()
44
```

CS 538 Spring 2008

# **Other Operations on Functions**

Since Python is interpreted, you can dynamically create and execute Python code.

The function **eval(string)** interprets **string** as a Python expression (in the current execution environment) and returns what is computed. For example,

```
>>> a=1;b=2
>>> eval('a+b')
```

3

Assignments are to local variables, even if a global exists. To *force* an assignment to refer to a global identifier, you use the declaration

#### global id

which tells Python that in this function *ia* should be considered global rather than local. For example,

```
>>> a=1;b=2
>>> def f():
... global a
... a=111;b=222
...
>>> f();print a,b
111 2
```

CS 538 Spring 2008

541

542

**exec(string)** executes **string** as arbitrary Python code (in the current environment):

>>> a=1;b=2

>>> exec('for op in "+-\*/":
print(eval("a"+op+"b"))')

3

-1

2

execfile(string) executes the
contents of the file whose
pathname is specified by string.
This can be useful in loading an
existing set of Python definitions.

```
The expression
     lambda args: expression
    creates an anonymous function
    with args as its argument list and
    expression as it body. For
    example.
    >>> (lambda a:a+1)(2)
    3
    And there are definitions of map.
    reduce and filter to map a
    function to a list of values, to
    reduce a list (using a binary
    function) and to select values
    from a list (using a predicate):
    >>> def double(a):
          return 2*a;
    . . .
    . . .
    >>> map(double, [1,2,3,4])
    [2, 4, 6, 8]
CS 538 Spring 2008
```

```
>>> def sum(a,b):
           return a+b
     . . .
     . . .
     >>> reduce(sum, [1, 2, 3, 4, 5])
     15
     >>> def even(a):
           return not(a%2)
     . . .
     >>> filter(even, [1,2,3,4,5])
     [2, 4]
CS 538 Spring 2008
```

# GENERATORS

Many languages, including Java, C# and Python provide iterators to index through a collection of values. Typically, a **next** function is provided to generate the next value and hasNext is used to test for termination.

Python provides generators, a variety of function (in effect a coroutine) to easily and cleanly generate the sequence of values required of an iterator.

In any function a yield (rather than a **return**) can provide a value and suspend execution. When the next value is needed (by an invisible call to **next**) the function is resumed at the point of the **yield**. Further yields generate successive values. Normal

termination indicates that hasNext is no longer true.

As a very simple example, the following function generates all the values in a list **L** except the initial value:

```
>>> def allButFirst(L):
```

for i in L[1:]: . . .

vield i . . .

>>> for j in allButFirst([1,2,3,4]): print j, . . .

234

The power of generators is their ability to create non-standard traversals of a data structure in a clean and compact manner.

545

As an example, assume we wish	Generators work in list comprehensions too:
<pre>to visit the elements of a list not in left-to-right or right-to-left order, but in an order that visits even positions first, then odd positions. That is we will first see L[0], then L[2], then L[4],, then L[1], L[3], We just write a generator that takes a list and produces the correct visit order: &gt;&gt;&gt; def even_odd(L):  ind = range(0,len(L),2)  ind = ind + range(1,len(L),2)  for i in ind:  yield L[i] Then we can use this generator wherever an iterator is needed: &gt;&gt;&gt; for j in even_odd([10,11,12,13,14]):  print j,  10 12 14 11 13</pre>	>>> [j for j in even_odd([11,12,13])] [11, 13, 12]
C6 538 Spring 2008	<b>49</b> CS 538 Spring 2008 <sup>67</sup>

#### I/O in Python

The easiest way to print information in Python is the **print** statement. You supply a list of values separated by commas. Values are converted to strings (using the **str()** function) and printed to standard out, with a terminating new line automatically included. For example,

#### >>> print "1+1=",1+1

#### 1+1= 2

If you don't want the automatic end of line, add a comma to the end of the print list:

```
>>> for i in range(1,11):
... print i,
...
1 2 3 4 5 6 7 8 9 10
```

For those who love C's **printf**, Python provides a nice formatting capability using a printf-like notation. The expression

#### format % tuple

formats a tuple of values using a format string. The detailed formatting rules are those of C's **printf**. Thus

>>> print "%d+%d=%d" % (10,20,10+20) 10+20=30

```
File-oriented I/O
  You open a file using
  open(name, mode)
  which returns a "file object."
  name is a string representing the
  file's path name; mode is a string
  representing the desired access
  mode('r' for read, 'w' for write,
  etc.).
  Thus
  >>> f=open("/tmp/f1","w");
  >>> f
  <open file '/tmp/f1', mode 'w' at</pre>
  decd8>
  opens a temp file for writing.
  The command
    f.read(n)
  reads n bytes (as a string).
```

```
f.read() reads the whole file into
a string. At end-of-file, f.read
returns the null string:
>>> f = open("/tmp/ttt","r")
>>> f.read(3)
'aaa'
>>> f.read(5)
' bbb '
>>> f.read()
'ccc\012ddd eee fff\012g h i\012'
>>> f.read()
1.1
f.readline() reads a whole line
of input, and f.readlines()
reads the whole input file into a
list of strings:
>>> f = open("/tmp/ttt","r")
>>> f.readline()
'aaa bbb ccc\012'
>>> f.readline()
```

```
CS 538 Spring 2008
```

553

```
'ddd eee fff\012'
>>> f.readline()
'g h i\012'
>>> f.readline()
>>> f = open("/tmp/ttt","r")
>>> f.readlines()
['aaa bbb ccc\012', 'ddd eee
fff\012', 'g h i\012']
f.write(string) Writes a string
to file object f; f.close() closes
a file object:
>>> f = open("/tmp/ttt","w")
>>> f.write("abcd")
>>> f.write("%d
                    %d"%(1,-1))
>>> f.close()
>>> f = open("/tmp/ttt","r")
>>> f.readlines()
['abcd1
           -111
```

**CLASSES IN PYTHON** 

CS 538 Spring 2008

Python contains a class creation mechanism that's fairly similar to what's found in C++ or Java.

There are significant differences though:

- All class members are public.
- Instance fields aren't declared. Rather, you just create fields as needed by assignment (often in constructors).
- There are class fields (shared by all class instances), but there are no class methods. That is, all methods are instance methods.

 All instance methods (including constructors) must explicitly provide an initial parameter that represents the object instance. This parameter is typically called self. It's roughly the equivalent of this in C++ or Java.

```
CS 538 Spring 2008
```

557

#### **Defining Classes**

You define a class by executing a class definition of the form

#### class name:

#### statement(s)

A class definition creates a class object from which class instances may be created (just like in Java). The statements within a class definition may be data members (to be shared among all class instances) as well as function definitions (prefixed by a **def** command). Each function must take (at least) an initial parameter that represents the class instance within which the function (instance method) will operate. For example,

CS 538 Spring 2008

class Example: cnt=1 def msg(self): print "Bo"+"o"\*Example.cnt+ "!"\*self.n >>> Example.cnt 1 >>> Example.msg <unbound method Example.msg>

**Example.msg** is unbound because we haven't created any instances of the **Example** class yet.

We create class instances by using the class name as a function: >>> e=Example()

>>> e.msg()
AttributeError: n

We get the AttributeError message regarding n because we haven't defined n yet! One way to do this is to just assign to it, using the usual field notation:

>>> e.n=1

```
>>> e.msg()
```

Boo!

>>> e.n=2;Example.cnt=2

```
>>> e.msg()
```

Booo!!

We can also call an instance method by making the class object an explicit parameter:

>>> Example.msg(e)

#### Booo!!

It's nice to have data members initialized when an object is created. This is usually done with a constructor, and Python allows this too.

```
A special method named
  init is called whenever an
object is created. This method
takes self as its first parameter;
other parameters (possibly made
optional) are allowed.
We can therefore extend our
Example class with a constructor:
class Example:
  cnt=1
  def init (self,nval=1):
    self.n=nval
  def msg(self):
    print "Bo"+"o"*Example.cnt+
           "!"*self.n
>>> e=Example()
>>> e.n
1
>>> f=Example(2)
>>> f.n
2
```

```
You can also define the equivalent
of Java's toString method by
defining a member function
named ___str__(self).
For example, if we add
```

of example, if we add

def \_\_str\_\_(self):
 return "<%d>"%self.n

tO Example,

then we can include **Example** objects in **print** statements:

```
>>> e=Example(2)
.
```

```
>>> print e
<2>
```

CS 538 Spring 2008

CS 538 Spring 2008

561

#### Inheritance

Like any language that supports classes, Python allows inheritance from a parent (or base) class. In fact, Python allows *multiple inheritance* in which a class inherits definitions from more than one parent.

When defining a class you specify parents classes as follows:

```
class name(parent classes):
    statement(s)
```

The subclass has access to its own definitions as well as those available to its parents. All methods are virtual, so the most recent definition of a method is always used.

```
class C:
  def DoIt(self):
      self.PrintIt()
  def PrintIt(self):
      print "C rules!"
```

```
class D(C):
  def PrintIt(self):
      print "D rules!"
  def TestIt(self):
        self.DoIt()
```

dvar = D() dvar.TestIt()

D rules!

If you specify more than one parent for a class, lookup is depth-first, left to right, in the list of parents provided. For example, given

#### class A(B,C): ...

we first look for a non-local definition in **B** (and its parents), then in **c** (and its parents).

#### CS 538 Spring 2008

#### 565

### **Operator Overloading**

You can overload definitions of all of Python's operators to apply to newly defined classes. Each operator has a corresponding method name assigned to it. For example, + uses \_\_add\_\_, - uses sub\_, etc.

CS 538 Spring 2008

Given class Triple: def \_\_init\_\_(self,A=0,B=0,C=0): self.a=A self.b=B self.c=C def \_\_str\_\_(self): return "(%d,%d,%d)"% (self.a,self.b,self.c) def \_\_add\_\_(self,other): return Triple(self.a+other.a, self.b+other.b, self.c+other.c) the following code t1=Triple(1,2,3)t2=Triple(4,5,6)print t1+t2 produces (5,7,9)

#### **Exceptions**

Python provides an exception mechanism that's guite similar to the one used by Java.

You "throw" an exception by using a **raise** statement:

#### raise exceptionValue

There are numerous predefined exceptions, including **OverflowError** (arithmetic overflow), **EOFError** (when endof-file is hit), **NameError** (when an undeclared identifier is referenced), etc.

CS 538 Spring 2008

567

```
You may define your own
exceptions as subclasses of the
predefined class Exception:
class badValue(Exception):
  def init (self, val):
     self.value=val
You catch exceptions in Python's
version of a try statement:
try:
  statement(s)
except exceptionName<sub>1</sub>, id<sub>1</sub>:
  statement(s)
except exceptionName, id,:
  statement(s)
As was the case in lava, an
exception raised within the try
body is handled by an except
clause if the raised exception
matches the class named in the
```

CS 538 Spring 2008

```
except clause. If the raised
exception is not matched by any
except clause, the next enclosing
try is considered, or the
exception is reraised at the point
of call.
For example, using our badValue
exception class,
 def sqrt(val):
  if val < 0.0:
      raise badValue(val)
  e1se.
      return cmath.sqrt(val)
try:
 print "Ans =",sqrt(-123.0)
except badValue,b:
  print "Can't take sqrt of",
         b.value
When executed, we get
Ans = Can't take sqrt of -123.0
```

CS 538 Spring 2008

569

#### Modules

Python contains a module feature that allows you to access Python code stored in files or libraries. If you have a source file mydefs.py the command

#### import mydefs

will read in all the definitions stored in the file. What's read in can be seen by executing

#### dir(mydefs)

To access an imported definition, you qualify it with the name of the module. For example,

#### mydefs.fct

accesses fct which is defined in module mydefs.

```
To avoid explicit qualification you
can use the command
from modulename import id<sub>1</sub>, id<sub>2</sub>,
...
This makes id<sub>1</sub>, id<sub>2</sub>, ... available
without qualification. For
example,
>>> from test import sqrt
>>> sqrt(123)
(11.0905365064+0j)
You can use the command
from modulename import *
to import (without qualification)
all the definitions in modulename.
```

#### THE Python Library JAVA 1.5/1.6 (TIGER JAVA) One of the great strengths of Java has been extended to include Python is that it contains a vast a variety of improvements, many number of modules (at least drawn from functional languages. several hundred) known Added features include: collectively as the *Python Library*. • Parametric polymorphism. What makes Python really useful Classes and interfaces may be is the range of prewritten parameterized using a type modules you can access. Included parameter. are network access modules. multimedia utilities. data base class List<T> { access, and much more. T head; See List<T> tail; } www.python.org/doc/lib Interfaces may also be for an up-to-date listing of what's parameterized. available. Enhanced loop iterators. for (v : myArray) { // each element of myArray // appears as a value of v } CS 538 Spring 2008 CS 538 Spring 2008 573

 Automatic boxing and unboxing of wrapper classes.

Conversion from **int** to **Integer** or **Integer** to **int** is now automatic.

- Typesafe enumerations.
   public enum Color {RED, BLUE, GREEN};
- Static imports.

You may import all static members of a class and use them without qualification. Thus you may now write **out.println** rather than **System.out.println**.

- · Variable argument methods.
- Formatted output using printf: out.printf("Ans = %3d",a+b);

# **Reading Assignment**

 Pizza Tutorial (linked from class web page)

CS 538 Spring 2008
# C#

C# is Microsoft's answer to Java. In most ways it is very similar to Java, with some C++ concepts reintroduced and some useful new features.

Similarities to Java include:

- C# is object-based, with all objected descended from class
   Object.
- Objects are created from classes using **new**. All objects are heapallocated and garbage collection is provided.
- All code is placed within methods which must be defined within classes.
- Almost all Java reserved words have C# equivalents (many are identical).

CS 538 Spring 2008

- Classes have single inheritance.
- C# generates code for a virtual machine to support cross-platform execution.
- Interfaces are provided to capture functionality common to many classes.
- Exceptions are very similar in form to Java's.
- Instance and static data within an object must be initialized at point of creation.

CS 538 Spring 2008

577

578

## C# IMPROVES UPON SOME JAVA FEATURES

• Operators as well as methods can be overloaded:

```
• Switch statements may be indexed by string literals.
```

- In a switch, fall-throughs to the next case are disallowed (if nonempty).
- · Goto's are allowed.
- Virtual methods must be marked.

• Persistent objects (that may be stored across executions) are available.

# C# Adds Useful Features

- *Events* and *delegates* are included to handle asynchronous actions (like keyboard or mouse actions).
- *Properties* allow user-defined read and write actions for fields. You can add get and set methods to the definition of a field. For example,

```
class Customer {
   private string name;
   public string Name {
    get { return name; }}
}
Customer c; ...
string s = c.Name;
```

```
CS 538 Spring 2008
```

When an object is needed, a primitive (int, char, etc.) or a struct will be automatically boxed or unboxed without explicit use of a wrapper class (like Integer or Character). Thus if method List.add expects an object, you may write List.add(123);

and **123** will be boxed into an **Integer** object automatically.

- Enumerations are provided: enum Color {Red, Blue, Green};
- Rectangular arrays are provided: int [,] multi = new int[5,5];
- Reference, out and variable-length parameter lists are allowed.
- Pointers may be used in methods marked unsafe.

• Indexers allow objects other than arrays to be indexed. The [] operator is overloadable. This allows you to define the meaning of

**obj[123]** or **obj["abc"]** within *any* class definition.

Collection classes may be directly enumerated:

foreach (int i in array) ...

• Fields, methods and constructors may be defined within a *struct* as well as a class. Structs are allocated within the stack instead of the heap, and are passed by value. For example:

struct Point {
 int x,y;
 void reset () {
 x=0; y=0; }
}

CS 538 Spring 2008

581

VERSION **3.0** of C# Adds Additional Features

```
• Implicitly Typed Local Variables
(Old form):
    int n = 5;
    string s = "CS 538 rules!";
    int[] nums =
        new int[] {1, 2, 3};
(New form):
    var n = 5;
    var s = "CS 538 rules!";
    var nums =
        new int[] {1, 2, 3};
```

```
    Lambda Expressions

  string[] arr =
   { "asdf", "pop", "crazy", "mine" };
  var sorted =
   arr.OrderBy(e => e[e.Length-1]);
 //sorted by last char in the string

    Object Initializers

 (Old form):
   Contact contact =
     new Contact();
   contact.LastName = "Magennis";
   contact.DateOfBirth =
    new DateTime(1973,12,09);
 (New form):
   Contact contact =
    new Contact {
     LastName = "Magennis",
     DateOfBirth =
      new DateTime(1973,12,09)
  };;
```

```
    Collection Initializers

   List<int> digits =
     new List<int> { 0, 1, 2,
    3, 4, 5, 6, 7, 8, 9 };
   List<Contact> contacts =
    new List<Contact> {
      new Contact {
         LastName = "Doherty",
         DOB =
          newDateTime(1989,1,1)},
      new Contact {
         LastName = "Wilcox",
         DOB =
          new DateTime(1987,3,3)}
   };

    Anonymous Types

   var anonType =
      new {X = 1, Y = 2};
```

CS 538 Spring 2008

585

586

 Implicitly Typed Arrays Old: int[] a = new int[] { 1, 10, 100, 1000 }; double[] b = new double[] { 1, 1.5, 2, 2.5 }; string[] c = new string[] { "hello",null, "world"}; New: var a = new[] { 1, 10, 100, 1000 }; var b = new[] { 1, 1.5, 2, 2.5 }; var c = new[] {"hello", null, "world"}; Automatic Properties Old: private string \_name; public string Name ſ get { return \_name; } set { \_name = value; } } New: public string Name { get; set; }

#### Pizza

Pizza is an extension to Java developed in the late 90s by Odersky and Wadler.

Pizza shows that many of the best ideas of functional languages can be incorporated into a "mainstream" language, giving it added power and expressability. Pizza adds to Java:

1. Parametric Polymorphism

Classes can be parameterized with types, allowing the creation of "custom" data types with full compile-time type checking.

CS 538 Spring 2008

### **PARAMETRIC POLYMORPHISM**

lava allows a form of polymorphism by defining container classes (lists, stacks, queues, etc.) in terms of values of type **Object**. For example, to implement a linked list we might use: class LinkedList { Object value: LinkedList next; Object head() {return value;} LinkedList tail(){return next;} LinkedList(Object 0) { value = 0; next = null;} LinkedList(Object 0, LinkedList L) { value = 0; next = L;} }

CS 538 Spring 2008

We use class **Object** because any object can be assigned to **Object** (all classes must be a subclass of **Object**).

Using this class, we can create a linked list of any subtype of **Object**.

But,

- We can't guarantee that linked lists are *type homogeneous* (contain only a single type).
- We must unbox **Object** types back into their "real" types when we extract list values.
- We must use wrapper classes like Integer rather than int (because primitive types like int aren't objects, and aren't subclass of Object).

For example, to use **LinkedList** to build a linked list of **int**s we do the following:

LinkedList L =

new LinkedList(new Integer(123));
int i =

((Integer) L.head()).intValue(); This is pretty clumsy code. We'd prefer a mechanism that allows us to create a "custom version" of LinkedList, based on the type we want the list to contain.

We can't just call something like

LinkedList(int) Or LinkedList(Integer) because types can't be passed as parameters.

*Parametric polymorphism* is the solution. Using this mechanism, we *can* use type parameters to

591

```
When linked list objects are
created (using new) no type
qualifiers are needed—the type of
the constructor's parameters are
used. We can create
LinkedList<int> L1 =
    new LinkedList(123);
int i = L1.head();
LinkedList<String> L2 =
    new LinkedList("abc");
String s = L2.head();
LinkedList<LinkedList<int> L3 =
    new LinkedList(L1);
int j = L3.head().head();
```

CS 538 Spring 2008

#### **Bounded Polymorphism**

In Pizza we can use interfaces to bound the type parameters a class will accept.

Recall our **Compare** interface:

interface Compare {

#### }

We can specify that a parameterized class will only takes types that implement **Compare**:

 In fact, we can improve upon how interfaces are defined and used.

Recall that in method **lessThan** we had to use parameters declared as type **Object** to be general enough to match (and accept) any object type. This leads to clumsy casting (with runtime correctness checks) when **lessThan** is implemented for a particular type:

}

CS 538 Spring 2008

593

```
Pizza allows us to parameterize
class definitions with type
parameters, so why not do the
same for interfaces?
In fact, this is just what Pizza
does. We now define compare as
interface Compare<T> {
  boolean lessThan(T o1, T o2);
}
Now class LinkedList is
class LinkedList<T implements
            Compare \langle T \rangle > \{ \dots \}
Given this form of interface
definition, no casting (from type
Object) is needed in classes that
implement Compare:
class IntCompare implements
  Compare<Integer> {
public boolean lessThan(Integer i1,
                        Integer i2){
return i1.intValue() <</pre>
        i2.intValue();}
}
```

```
First-class Functions in Pizza
```

In Java, functions are treated as constants that may appear only in classes.

To pass a function as a parameter, you must pass a class that contains that function as a member. For example,

```
class Fct {
   int f(int i) { return i+1; }
}
class Test {
   static int call(Fct g, int arg)
      { return g.f(arg); }
```

CS 538 Spring 2008

597

}

598

Changing the value of a function is even nastier. Since you can't assign to a member function, you have to use subclassing to override an existing definition: class Fct2 extends Fct { int f(int i) { return i+111; } } Computing new functions during executions is nastier still, as Java doesn't have any notion of a lambda-term (that builds a new function).

Pizza makes functions first-class, as in ML. You can have function parameters, variables and return values. You can also define new functions within a method.

The notation used to define the type of a function value is

 $(T_1, T_2, \ldots) \to T_0$ 

This says the function will take the list ( $\mathbf{T}_1, \mathbf{T}_2, \ldots$ ) as it arguments and will return  $\mathbf{T}_0$  as its result.

Thus

(int)->int

represents the type of a method like

int plus1(int i) {return i+1;}

CS 538 Spring 2008

The notation used by Java for fixed functions still works. Thus static int f(int i){return 2\*i;}; denotes a function constant. f. The definition static (int)->int g = f;defines a field of type (int)->int named **g** that is initialized to the value of f. The definition static int call((int)->int f, int i) {return f(i);}; defines a constant function that takes as parameters a function value of type (int)->int and an int value. It calls the function parameter with the **int** parameter and returns the value the function computes.

Pizza also has a notation for anonymous functions (function literals), similar to **fn** in ML and **lambda** in Scheme. The notation fun  $(T_1 a_1, T_2 a_2, \ldots) \rightarrow T_0$ {Body} defines a nameless function with arguments declared as  $(T_1 a_1, T_2 a_2, \ldots)$  and a result type of  $\mathbf{T}_0$ . The function's body is computed by executing the block {Body}. For example, static (int)->int compose( (int)->int f, (int)->int g){ return fun (int i) -> int {return f(g(i));}; }

CS 538 Spring 2008

601

CS 538 Spring 2008

defines a method named compose. It takes as parameters two functions, f and g, each of type (int)->int.

The function returns a function as its result. The type of the result is (int)->int and its value is the composition of functions f and g: return f(g(i));

Thus we can now have a call like

compose(f1, f2)(100)

which computes f1(f2(100)).

```
With function parameters, some familiar functions can be readily programmed:
```

}; }

603

```
And we can make such operations
    polymorphic by using parametric
    polymorphism:
    class Map<T> {
      private static T dummy;
      Map(T val) {dummy=val;};
       static T[] map((T)->T f,
                        T[] a){
          T [] ans = (T[]) a.clone();
          for (int i=0;i<a.length;i++)</pre>
              ans[i]=f(a[i]);
          return ans;
      };
    }
CS 538 Spring 2008
                                          605
```

## Algebraic Data Types

Pizza also provides "algebraic data types" which allow a type to be defined as a number of cases. This is essentially the patternoriented approach we saw in ML.

A list is a good example of the utility of algebraic data types. Lists come in two forms, null and non-null, and we must constantly ask which form of list we currently have. With patterns, the need to consider both forms is enforced, leading to a more reliable programming style.

In Pizza, patterns are modeled as "cases" and grafted onto the existing switch statement (this formulation is a bit clumsy):

```
CS 538 Spring 2008
```

```
class List {
   case Nil;
   case Cons(char head,
       List tail);
   int length(){
      switch(this){
      case Nil: return 0;
      case Cons(char x, List t):
        return 1 + t.length();
   }
  }
}
```

```
And guess what! We can use
parametric polymorphism along
with algebraic data types:
class List<T> {
   case Nil;
   case Cons(T head,
        List<T> tail);
   int length() {
      switch(this) {
      case Nil: return 0;
      case Cons(T x, List<T> t):
        return 1 + t.length();
    }
  }
}
```
