CS 701

Charles N. Fischer

Fall 2001

http://www.cs.wisc.edu/~fischer/cs701.html
Class Meets

Tuesdays & Thursdays, 9:30 — 10:45
1263 Computer Sciences

Instructor

Charles N. Fischer
5397 Computer Sciences
Telephone: 262-6635
E-mail: fischer@cs.wisc.edu
Office Hours:
10:30 - Noon, Mondays & Wednesdays, or by appointment
Teaching Assistant
James Nugent
1308 Computer Sciences
Telephone:  262-6602
E-mail:       damion@ cs.wisc.edu
Office Hours:
   1:30 - 2:30 Tuesdays,
   10:30 - 11:30 Fridays,
   or by appointment
Key Dates

- September 25: Project 1 due
- October 23: Project 2 due (tentative)
- October 30: Midterm (tentative)
- November 20: Project 3 due (tentative)
- December 13: Project 4 due
- December ??: Final Exam, date to be determined
Class Text

There is no required text. Handouts and Web-based reading will be used.

Suggested reference:

Instructional Computers

Departmental SPARC Processors (nova1- nova60)

You may use your own workstation if it is has a SPARC processor
  (test using `dmesg | grep cpu`)

Otherwise log onto a SPARC processor to do SPARC-specific assignments
CS 701 Projects

1. SPARC Code Optimization
2. Global Register Allocation (using Graph Coloring)
3. Global Code Optimizations
4. Individual Research Topics
Academic Misconduct Policy

- You must do your assignments—no copying or sharing of solutions
- You may discuss general concepts and ideas
- All cases of Misconduct must be reported.
- Penalties may be severe.
Reading Assignment

• Get Handout #1 (SPARC Architecture Information) and Handout #2 (Chapter 15, Code Optimization) from Dolt.

• Review Handout #1 and read section 15.2 of Chapter 15.

• Read Assignment #1
Overview of Course Topics

1. Register Allocation

   Local Allocation
   Avoid unnecessary loads and stores within a basic block. Remember and reuse register contents. Consider effects of aliasing.

   Global Allocation
   Allocate registers within a single subprogram. Choose “most profitable” values. Map several values to the same register.

   Interprocedural Allocation
   Avoid saves and restores across calls. Share globals in registers.
2. Code Scheduling

We can reorder code to reduce latencies and to maximize ILP (Instruction Level Parallelism). **We must respect** data dependencies and control dependencies.

```
 ld  [a],%r1
 add  %r1,1,%r2
 mov  3,%r3
mov  3,%r3
```

(before)

```
 ld  [a],%r1
 add  %r1,1,%r2
```

(after)
3. Automatic Instruction Selection

How do we map an IR (Intermediate Representation) into Machine Instructions?

Can we guarantee the best instruction sequence?

Idea—Match instruction patterns (represented as trees) against an IR that is a low-level tree. Each match is a generated instruction; the best overall match is the best instruction sequence.
Example:
\[ a = b + c + 1; \]

In IR tree form:

```
    =
   /|
  /  \
/    \
|     |
|     +
|   /|
|  /  \
| /    \
|/      |
+--------
   ↑     ↑
  ↑      ↑
  ↓      ↓
  ↓      ↓
  ↓      ↓
%fp    b_offset

+ 1
 +
 a_adr
```

Generated code:

```
ld  [%fp+b_offset],%r1
ld  [c adr],%r2
add %r1,%r2,%r3
add %r3,1,%r4
st  %r4,[a adr]
```

Why use four different registers?
4. Peephole Optimization

Inspect generated code sequences and replace pairs/triples/tuples with better alternatives.

\[\begin{align*}
\text{ld} & \quad [a],%r1 & \quad \text{ld} & \quad [a],%r1 \\
\text{mov} & \quad \text{const},%r2 & \quad \text{add} & \quad %r1,\text{const},%r3 \\
\text{add} & \quad %r1,%r2,%r3 & \quad \text{add} & \quad %r1,%r2,%r3 \\
\text{(before)} & & \text{(after)} & \\
\text{mov} & \quad 0,%r1 & \quad \text{OP} & \quad %g0,%r2,%r3 \\
\text{OP} & \quad %r1,%r2,%r3 & \quad \text{OP} & \quad %r1,%r2,%r3 \\
\text{(before)} & & \text{(after)} & 
\end{align*}\]

But why not just generate the better code sequence to begin with?
5. Cache Improvements

We want to access data & instructions from the L1 cache whenever possible; misses into the L2 cache (or memory) are expensive!

We will layout data and program code with consideration of cache sizes and access properties.

6. Local & Global Optimizations

Identify unneeded or redundant code.
Decide where to place code.
Worry about debugging issues (how reliable are current values and source line numbers after optimization?)
7. Program representations

- Control Flow Graphs
- Program Dependency Graphs
- Static Single Assignment Form (SSA)
  
  Each program variable is assigned to in only one place.
  After an assignment \( x_i = y_j \), the relation \( x_i = y_j \) always holds.

Example:

```plaintext
if (a)          if (a)  
     x = 1        x_1 = 1
else x = 2;     else x_2 = 2;
print(x)    x_3 = \phi(x_1, x_2)
```

```plaintext
print(x_3)
```
8. Data Flow Analysis

Determine invariant properties of subprograms; analysis can be extended to entire programs.

Model abstract execution.

Prove correctness and efficiency properties of analysis algorithms.
Review of Compiler Optimizations

1. Redundant Expression Elimination (Common Subexpression Elimination)
   Use an address or value that has been previously computed. Consider control and data dependencies.

2. Partially Redundant Expression (PRE) Elimination
   A variant of Redundant Expression Elimination. If a value or address is redundant along some execution paths, add computations to other paths to create a fully redundant expression (which is then removed).

Example:

```c
if (i > j)
    a[i] = a[j];
a[i] = a[i] * 2;
```
3. Constant Propagation

If a variable is known to contain a particular constant value at a particular point in the program, replace references to the variable at that point with that constant value.

4. Copy Propagation

After the assignment of one variable to another, a reference to one variable may be replaced with the value of the other variable (until one or the other of the variables is reassigned).

(This may also “set up” dead code elimination. Why?)

5. Constant Folding

An expression involving constant (literal) values may be evaluated and simplified to a constant result value. Useful when constant propagation is performed.
6. Dead Code Elimination

Expressions or statements whose values or effects are unused may be eliminated.

7. Loop Invariant Code Motion

An expression that is invariant in a loop may be moved to the loop’s header, evaluated once, and reused within the loop. Safety and profitability issues may be involved.

8. Scalarization (Scalar Replacement)

A field of a structure or an element of an array that is repeatedly read or written may be copied to a local variable, accessed using the local, and later (if necessary) copied back.

This optimization allows the local variable (and in effect the field or array component) to be allocated to a register.
9. Local Register Allocation
Within a basic block (a straight line sequence of code) track register contents and reuse variables and constants from registers.

10. Global Register Allocation
Within a subprogram, frequently accessed variables and constants are allocated to registers. Usually there are many more register candidates than available registers.

11. Interprocedural Register Allocation
Variables and constants accessed by more than one subprogram are allocated to registers. This can greatly reduce call/return overhead.
12. Register Targeting
Compute values directly into the intended target register.

13. Interprocedural Code Motion
Move instructions across subprogram boundaries.

14. Call Inlining
At the site of a call, insert the body of a subprogram, with actual parameters initializing formal parameters.

15. Code Hoisting and Sinking
If the same code sequence appears in two or more alternative execution paths, the code may be hoisted to a common ancestor or sunk to a common successor. (This reduces code size, but does not reduce instruction count.)
16. Loop Unrolling

Replace a loop body executed N times with an expanded loop body consisting of M copies of the loop body. This expanded loop body is executed N/M times, reducing loop overhead and increasing optimization possibilities within the expanded loop body.

17. Software Pipelining

A value needed in iteration i of a loop is computed during iteration i-1 (or i-2, ...). This allows long latency operations (floating point divides and square roots, low hit-ratio loads) to execute in parallel with other operations. Software pipelining is sometimes called symbolic loop unrolling.
18. Strength Reduction
Replace an expensive instruction with an equivalent but cheaper alternative. For example a multiplication may be replaced by a series of additions, or a list append may be replaced by a series of cons operations.

19. Data Cache Optimizations

• Locality Optimizations
  Cluster accesses of data values both spacially (within a cache line) and temporally (for repeated use).
  Loop interchange and loop tiling improve temporal locality.

• Conflict Optimizations
  Adjust data locations so that data used consecutively and repeatedly don’t share the same cache location.
20. Instruction Cache Optimizations

Instructions that are repeatedly re-executed should be accessed from the instruction cache rather than the secondary cache or memory. Loops and “hot” instruction sequences should fit within the cache.

Temporally close instruction sequences should not map to conflicting cache locations.
SPARC Overview

- SPARC is an acronym for Scalable Processor ARCHitecture
- SPARC processors are load/store RISC processors
  Load/store means only loads and stores access memory directly.
  RISC (Reduced Instruction Set Computer) means the architecture is simplified with a limited number of instruction formats and addressing modes.
- **Instruction format:**
  
  \[ \text{add} \ %r1,\ %r2,\ %r3 \]
  
  Registers are prefixed with a \%
  
  Result is stored into last operand.

- \[ \text{ld} \ [\text{adr}],\ %r1 \]
  
  Memory addresses (used only in loads and stores) are enclosed in brackets

- **Distinctive features include** Register Windows and Delayed Branches
Register Windows

The SPARC provides 32 general-purpose integer registers, denoted as %r0 through %r31.

These 32 registers are subdivided into 4 groups:

- **Globals:** %g0 to %g7
- **In registers:** %i0 to %i7
- **Locals:** %l0 to %l7
- **Out registers:** %o0 to %o7

There are also 32 floating-point registers, %f0 to %f31.

A SPARC processor has an implementation-dependent number of register windows, each consisting of 16 distinct registers. The "in", "local" and "out" registers that are accessed in a procedure depend on the current register window. The "global"
registers are independent of the register windows (as are the floating-point registers).

A register window may be pushed or popped using SPARC save and restore instructions.

After a register window push, the “out” registers become “in” registers and a fresh set of “local” and “out” registers is created:

**Before save:**

<table>
<thead>
<tr>
<th>In</th>
<th>Local</th>
<th>Out</th>
</tr>
</thead>
<tbody>
<tr>
<td>In (old)</td>
<td>Local (old)</td>
<td>In (new)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Local (new)</td>
</tr>
</tbody>
</table>

**After save**
Why the overlap between “in” and “out” registers? It’s a convenient way to pass parameters—the caller puts parameter values in his “out” registers. After a call (and a save) these values are automatically available as “in” registers in the newly created register window.

SPARC procedure calls normally advance the register window. The "in" and "local" registers become hidden, and the "out" registers become the "in" registers of the called procedure, and new "local" and "out" registers become available.

A register window is advanced using the save instruction, and rolled back using the restore instruction. These instructions are separate from the procedure call and return instructions, and can sometimes be optimized away.
For example, a leaf procedure—one that contains no calls—can be compiled without use of save and restore if it doesn’t need too many registers. The leaf procedure must then make do with the caller’s registers, modifying only those the caller treats as volatile.
Register Conventions

Global Registers

%g0 is unique: It always contains 0 and can never be changed.

%g1 to %g7 have global scope (they are unaffected by save and restore instructions)

%g1 to %g4 are volatile across calls; they may be used between calls.

%g5 to %g7 are reserved for special use by the SPARC ABI (application binary interface)

Local Registers

%l0 to %l7

May be freely used; they are unaffected by deeper calls.
In Registers

These are also the caller’s out registers; they are unaffected by deeper calls.

%i0
Contains incoming parameter 1.
Also used to return function value to caller.

%i1 to %i5
Contain incoming parameters 2 to 6 (if needed); freely usable otherwise.

%i6 (also denoted as %fp)
Contains frame pointer (stack pointer of caller); it must be preserved.

%i7
Contains return address - 8 (offset due to delay slot); it must be preserved.
Out Registers

Become the in registers for procedures called from the current procedure.

%00

Contains outgoing parameter 1.

It also contains the value returned by the called procedure.

It is volatile across calls; otherwise it is freely usable.

%01 to %05

Contain outgoing parameters 2 to 6 as needed.

These are volatile across calls; otherwise they are freely usable.
%o6 (also denoted as %sp)

Holds the stack pointer (and becomes frame pointer of called routines)

It is reserved; it must always be valid (since TRAPs may modify the stack at any time).

%o7

Is volatile across calls.

It is loaded with address of caller on a procedure call.
Special SPARC Instructions

save  \%r1,\%r2,\%r3
save  \%r1,\texttt{const},\%r3

This instruction pushes a register window and does an add instruction (\%r3 = \%r1+\%r2). Moreover, the operands (\%r1 and \%r2) are from the old register window, while the result (\%r3) is in the new window.

Why such an odd definition?
It's ideal to allocate a new register window and push a new frame.

In particular,

save  \%sp,\texttt{\,-\,frameSize},\%sp

pushes a new register window. It also adds \texttt{\,-\,frameSize} (the stack grows downward) to the old stack pointer, initializing the new stack pointer. (The old stack pointer becomes the current frame pointer)
restore %r1,%r2,%r3

restore %r1,const,%r3

This instruction pops a register window and does an add instruction (%r3 = %r1+%r2). Moreover, the operands (%r1 and %r2) are from the current register window, while the result (%r3) is in the old window.

Why such an odd definition?

It’s ideal to release a register window and place a result in the return register (%o0).

In particular,

    restore %r1,0,%o0

pops a register window. It also moves the contents of %r1 to %o0 (in the caller’s register window).
**call label**

This instruction branches to label and puts the address of the call into register %07 (which will become %i7 after a save is done).

**ret**

This instruction returns from a subprogram by branching to %i7+8. Why 8 bytes after the address of the call? SPARC processors have delayed branch instructions, so the instruction immediately after a branch (or a call) is executed before the branch occurs! Thus two instructions after the call is the normal return point.
mov  const, %r1

You can load a small constant (13 bits or less) into a register using a mov. (mov is actually implemented as an or of const with %g0).

But how do you load a 32 bit constant? One instruction (32 bits long) isn’t enough. Instead you use:

sethi  %hi(const), %r1
or  %r1, %lo(const), %r1

That is, you extract the high order 22 bits of const (using %hi, an assembler operation). sethi fills in these 22 bits into %r1, clearing the lowest 10 bits. Then %lo extracts the 10 low order bits of const, which are or-ed into %r1.
Loading a 64 bit constant (in SPARC V9, which is a 64 bit processor) is far nastier:

sethi %uhi(const),%r_{tmp}
or %r_{tmp},%ulo(const),%r_{tmp}
sllx %r_{tmp},32,%r_{tmp}
sethi %hi(const),%r
or %r,%lo(const),%r
or %r_{tmp},%r,%r
Delayed Branches

In the SPARC, transfers of control (branches, calls and returns) are delayed. This means the instruction after the branch (or call or return) is executed before the transfer of control.

For example, in SPARC code you often see

```
ret
restore
```

The register window restore occurs first, then a return to the caller occurs.

Another example is

```
call subr
mov 3, %00
```

The load of subr’s parameter is placed after the call to subr. But the mov is done before subr is actually called.
Why are Delayed Branches Part of the SPARC Architecture?

Because of pipelining, several instructions are partially completed before a branch instruction can take effect. Rather than lose the computations already done, one (or more!) partially completed instructions can be allowed to complete before a branch takes effect.
How does a Compiler Exploit Delayed Branches?

A peephole optimizer or code scheduler looks for an instruction logically before the branch that can be placed in the branch’s delay slot. The instruction should not affect a conditional branch’s branch decision.

```
mov 3, %o0      call subr
call subr       mov 3, %o0
nop            (before)      (after)
```
Another possibility is to “hoist” the target instruction of a branch into the branch’s delay slot.

```
call subr      call subr+4
nop            mov 100,%l1
...            ...
subr:          subr:
    mov 100,%l1    mov 100,%l1
(before)                 (after)
```

Hoisting branch targets doesn’t work for conditional branches—we don’t want to move an instruction that is executed sometimes (when the branch is taken) to a position where it is always executed (the delay slot).
Annulled Branches

An annulled branch (denoted by a “,a” suffix) executes the instruction in the delay slot if the branch is taken, but ignores the instruction in the delay slot if the branch isn’t taken.

With an annulled branch, a target of a conditional branch can be hoisted into the branch’s delay slot.

```
bz  else
nopl mov 100,%l1
! then code
! then code
... ...
else: else:
    mov 100,%l1 mov 100,%l1
(before) (after)
```
SPARC Frame Layout (on Run-Time Stack)

The Stack Grows Downward

<table>
<thead>
<tr>
<th>Caller's Frame</th>
<th>%fp (old %sp)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Local Variables</td>
<td></td>
</tr>
<tr>
<td>alloca() space</td>
<td></td>
</tr>
<tr>
<td>Memory Temps &amp; Saved FP Registers</td>
<td></td>
</tr>
<tr>
<td>Parms past 6</td>
<td></td>
</tr>
<tr>
<td>Parms 1 to 6 (memory home)</td>
<td></td>
</tr>
<tr>
<td>Address of return value</td>
<td></td>
</tr>
<tr>
<td>Register Window Overflow (16 words)</td>
<td>%sp</td>
</tr>
</tbody>
</table>

Minimum frame Size (in gcc) is 112 bytes! (16+1+6+4 words, double aligned)
Examples of SPARC Code

```c
int incr(int i)
{
    return i+1;
}
```

Unoptimized:
```
incr:
    save   %sp, -112, %sp
    st     %i0, [%fp+68]
    ld     [%fp+68], %o1
    add    %o1, 1, %o0
    mov    %o0, %i0
    b      .LL2
    nop

    .LL2:
    ret
    restore
```
int main()
{
    int a;
    return incr(a);
}

Unoptimized:
main:
    save %sp, -120, %sp
    ld [%fp-20], %o0
    call incr, 0
    nop
    mov %o0, %i0
    b .LL3
    nop
    .LL3:
    ret
    restore
int incr(int i) {
    return i+1; }

Optimized:
    incr:
        retl
        add   %o0, 1, %o0

int    main(){
    int a;
    return incr(a);}

Optimized:
    main:
        save   %sp, -112, %sp
! Where is a ????
        call    incr, 0
        nop
        ret
        restore %g0, %o0, %o0
With More Extensive Optimization (including inlining) we get:

```
incr:
  retl
  add %o0, 1, %o0

main:
  retl
  add %o0, 1, %o0
```
Reading Assignment

“On the Fly” Local Register Allocation

Allocate registers as needed during code generation.
Partition registers into 3 classes.

- Allocatable
  Explicitly allocated and freed; used to hold a variable, literal or temporary.
  On SPARC: Local registers & unused In registers.

- Reserved
  Reserved for specific purposes by OS or software conventions.
  On SPARC: %fp, %sp, return address register, argument registers, return value register.
• Work

Volatile—used in short code sequences that need to use a register.
On SPARC: \%g1 to \%g4, unused out registers.

Register Targeting

Allow “end user” of a value to state a register preference in AST or IR.

or

Use Peephole Optimization to eliminate unnecessary register moves.

or

Use preferencing in a graph coloring register allocator.
Register Tracking

Improve upon standard getReg/freeReg allocator by tracking (remembering) register contents.

Remember the value(s) currently held within a register; store information in a Register Association List.

Mark each value as Saved (in memory) or Unsaved (in memory).

Each value in a register has a Cost. This is the cost (in instructions) to restore the value to a register.
The cost of allocating a register is the sum of the costs of the values it holds.

\[
\text{Cost( register )} = \sum_{\text{values} \in \text{register}} \text{cost(values)}
\]

When we allocate a register, we will choose the cheapest one.

If 2 registers have the same cost, we choose that register whose values have the most distant next use.

(Why most distant?)
Costs for the SPARC

0  Dead Value
1  Saved Local Variable
1  Small Literal Value (13 bits)
2  Saved Global Variable
2  Large Literal Value (32 bits)
2  Unsaved Local Variable
4  Unsaved Global Variable
Register Tracking Allocator

reg getReg() {
    if ( ∃ r ∈ regSet and cost(r) == 0)
        choose(r)
    else {
        c = 1;
        while(true) {
            if ( ∃ r ∈ regSet and cost(r) == c){
                choose r with cost(r) == c and
                most distant next use of
                associated values;
                break;
            }
            c++;
        }
        Save contents of r as necessary;
    }
    return r;
}
• Once a value becomes dead, it may be purged from the register association list without any saves.

• Values no longer used, but unsaved, can be purged (and saved) at zero cost.

• Assignments of a register to a simple variable may be delayed—just add the variable to the Register’s Association List entry as unsaved.

The assignment may be done later or made unnecessary (by a later assignment to the variable)

• At the end of a basic block all unsaved values are stored into memory.
Example

```c
int a, b, c, d; // Globals
a = 5;
b = a + d;
c = b - 7;
b = 10;
```

Naive Code

```
mov 5,%10
st  %10,[a]
ld  [a],%10
ld  [d],%11
add %10,%11,%10
st  %10,[b]
ld  [b],%10
sub %10,7,%10
st  %10,[c]
mov 10,%10
st  %10,[b]
```

18 instructions are needed (memory references take 2 instructions)
## With Register Tracking

<table>
<thead>
<tr>
<th>Instruction Generated</th>
<th>%10</th>
<th>%11</th>
</tr>
</thead>
<tbody>
<tr>
<td>mov 5,%10</td>
<td>5(S)</td>
<td></td>
</tr>
<tr>
<td>! Defer assignment to a</td>
<td>5(S), a(U)</td>
<td></td>
</tr>
<tr>
<td>ld [d], %11</td>
<td>5(S), a(U)</td>
<td>d(S)</td>
</tr>
<tr>
<td>!d unused after next inst</td>
<td></td>
<td></td>
</tr>
<tr>
<td>add %10,%11,%11</td>
<td>5(S), a(U)</td>
<td>b(U)</td>
</tr>
<tr>
<td>!b is dead after next inst</td>
<td></td>
<td></td>
</tr>
<tr>
<td>sub %11,7,%11</td>
<td>5(S), a(U)</td>
<td>c(U)</td>
</tr>
<tr>
<td>! %11 has lower cost</td>
<td></td>
<td></td>
</tr>
<tr>
<td>st %11, [c]</td>
<td>5(S), a(U)</td>
<td></td>
</tr>
<tr>
<td>mov 10, %11</td>
<td>5(S), a(U)</td>
<td>b(U), 10(S)</td>
</tr>
<tr>
<td>! save unsaved values</td>
<td></td>
<td></td>
</tr>
<tr>
<td>st %10, [a]</td>
<td></td>
<td>b(U), 10(S)</td>
</tr>
<tr>
<td>st %11,[b]</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

12 instructions (rather than 18)
Pointers, Arrays and Reference Parameters

When an array, reference parameter or pointed-to variable is read, all unsaved register values that might be aliased must be stored.

When an array, reference parameter or pointed-to variable is written, all unsaved register values that might be aliased must be stored, then cleared from the register association list.

Thus if \( a[3] \) is in a register and \( a[i] \) is assigned to, \( a[3] \) must be stored (if unsaved) and removed from the association list.
Optimal Expression Tree Translation—Sethi-Ullman Algorithm

Goal: Translate an expression tree using the fewest possible registers.

Approach: Mark each tree node, \( N \), with an Estimate of the minimum number of registers needed to translate the tree rooted by \( N \).

Let \( RN(N) \) denote the Register Needs of node \( N \).
In a Load/Store architecture (ignoring immediate operands):

\[ \text{RN(leaf)} = 1 \]

\[ \text{RN(Op)} = \]

\[ \text{If } \text{RN(Left)} = \text{RN(Right)} \]
\[ \text{Then } \text{RN(Left)} + 1 \]
\[ \text{Else } \text{Max}(\text{RN(Left)}, \text{RN(Right)}) \]

Example:

\[ \begin{array}{c}
\text{A}^1 \quad \text{B}^1 \\
\text{C}^1 \quad \text{D}^1 \\
\text{E}^1 \quad \text{F}^1
\end{array} \]

\[ \begin{array}{c}
+^3 \\
2 \\
+^3 \\
2 \\
\times^2
\end{array} \]
Key Insight of SU Algorithm

Translate subtree that needs more registers first.

Why?

After translating one subtree, we’ll need a register to hold its value.

If we translate the more complex subtree first, we’ll still have enough registers to translate the less complex expression (without spilling register values into memory).
Specification of SU Algorithm

TreeCG(tree *T, regList RL);

Operation:

- Translate expression tree T using only registers in RL.
- RL must contain at least 2 registers.
- Result of T will be computed into head(RL).
Summary of SU Algorithm

if T is a node (variable or literal)
   load T into R1 = head(RL)
else (T is a binary operator)
   Let R1 = head(RL)
   Let R2 = second(RL)
   if RN(T.left) >= Size(RL) and
      RN(T.right) >= Size(RL)
      (A spill is unavoidable)
      TreeCG(T.left, RL)
      Store R1 into a memory temp
      TreeCG(T.right, RL)
      Load memory temp into R2
      Generate (OP R2,R1,R1)
   elsif RN(T.left) >= RN(T.right)
      TreeCG(T.left, RL)
      TreeCG(T.right, tail(RL))
      Generate (OP R1,R2,R1)
   else
      TreeCG(T.right, RL)
      TreeCG(T.left, tail(RL))
      Generate (OP R2,R1,R1)
Example (with Spilling)

Assume only 2 Registers;
RL = [\%10,\%11]

We Translate the left subtree first (using 2 registers), store its result into memory, translate the right subtree, reload the left subtree’s value, then do the final operation.
ld  [A], %l0
ld  [B], %l1
sub  %l0,%l1,%l0
st  %l0, [temp]
ld  [C], %l0
ld  [D], %l1
add  %l0,%l1,%l0
ld  [temp], %l1
add  %l1,%l0,%l0
Larger Example

Assume 3 Registers;
RL = [%10, %11, %12]

Since right subtree is more complex, it is translated first.
ld  [C], %10
ld  [D], %11
add  %10,%11,%10
ld  [E], %11
ld  [F], %12
mul  %11,%12,%11
add  %10,%11,%10
ld  [A], %11
ld  [B], %12
sub  %11,%12,%11
add  %11,%10,%10
Refinements & Improvements

- Register needs rules can be modified to model various architectural features.

For example, Immediate operands, that need not be loaded into registers, can be modeled by the following rule:

\[ \text{RN(literal)} = 0 \text{ if literal may be used as an immediate operand} \]

- Commutativity & Associativity of operands may be exploited:
Is Minimizing Register Use Always Wise?

SU minimizes the number of registers used but at the cost of reduced ILP.

Since only 2 registers are used, there is little possibility of parallel evaluation.
When more registers are used, there is often more potential for parallel evaluation:

```
                +
               /
        +        +
       /          /
      4          4
     /            /
    A           B
```

Here as many as four registers may be used to increase parallelism.
Reading Assignment

- Read Section 15.3 (Register Allocation and Temporary Management) from Chapter 15
- Get Class Handout 3 from DOIT.
- Read Chaitin’s paper, “Register Allocation via Coloring.”
Optimal Translation for DAGs is Much Harder

If variables or expression values may be shared and reused, optimal code generation becomes NP-Complete.

Example: $a+b*(c+d)+a*(c+d)$

We must decide how long to hold each value in a register. Best orderings may “skip” between subexpressions

Scheduling Expression Trees

The Sethi-Ullman Algorithm minimizes register usage, without regard to code scheduling.

On machines with Delayed Loads, we also want to avoid stalls.
What is a Delayed Load?

Most pipelined processors require a delay of one or more instructions between a load of register R and the first use of R.

If a register is used “too soon,” the processor may stall execution until the register value becomes available.

ld   [a],%r1
add  %r1,1,%r1 ← Stall!

We try to place an instruction that doesn’t use register R immediately after a load of R.
This allows useful work instead of a wasteful stall.
The Sethi-Ullman Algorithm generates code that will stall:

\[
\begin{align*}
+^2 & \quad +^2 \\
A^1 & \quad B^1 \\
C^1 &
\end{align*}
\]

\[
\begin{align*}
\text{ld} & \quad [A], \%10 \\
\text{ld} & \quad [B], \%11 \\
\text{add} & \quad \%10, \%11, \%10 \\
\text{ld} & \quad [C], \%11 \\
\text{add} & \quad \%10, \%11, \%10
\end{align*}
\]

Stall!

Stall!

In fact, if we use the fewest possible registers, stalls are Unavoidable!
**Why?**

Loads increase the number of registers in use.

Binary operations decrease the number of registers in use (2 Operands, 1 Result).

The load that brings the number of registers in use up to the minimum number needed must be followed by an operator that uses the just-loaded value. This implies a stall.

We’ll need to allocate an extra register to allow an independent instruction to fill each delay slot of a load.
Extended Register Needs

Abbreviated as $\text{ERN}$

$\text{ERN(Identifier)} = 2$

$\text{ERN(Literal)} = 1$

$\text{ERN(Op)} =$

If $\text{ERN(Left)} = \text{ERN(Right)}$

Then $\text{ERN(Left)} + 1$

Else $\text{Max}(\text{ERN(Left)}, \text{ERN(Right)})$

Example

![Diagram of Extended Register Needs example]
Idea of the Algorithm

1. Generate instructions in the same order as Sethi-Ullman, but use Pseudo-Registers instead of actual machine registers.

2. Put generated instructions into a “Canonical Order” (as defined below).

What are Pseudo-Registers?

They are unique temporary locations, unlimited in number and generated as needed, that are used to model registers prior to register allocation.
Canonical Form for Expression Code

(Assume R registers will be used)

Desired instruction ordering:
1. R load instructions
2. Pairs of Operator/Load instructions
3. Remaining operators

This canonical form is obtained by “sliding” load instructions upward (earlier) in the original code ordering.

Note that:

- Moving loads upward is always safe, since each pseudo-register is assigned to only once.
- No more than R registers are ever live.
Example

Let $R = 3$, the minimum needed for a delay-free schedule.

Put into Canonical Form:

(Before Register Assignment)

- $ld \ [B], \ PR1$
- $ld \ [C], \ PR2$
- $ld \ [D], \ PR4$
- $add \ PR1,PR2,PR3$
- $ld \ [A], \ PR6$
- $add \ PR3,PR4,PR5$
- $add \ PR6,PR5,PR7$

(After Register Assignment)

- $ld \ [B], \ %10$
- $ld \ [C], \ %11$
- $ld \ [D], \ %12$
- $add \ %10,%11,%10$
- $ld \ [A], \ %11$
- $add \ %10,%12,%10$
- $add \ %11,%10,%10$

No Stalls!
Does This Algorithm Always Produce a Stall-Free, Minimum Register Schedule?

Yes—if one exists!

For very simple expressions (one or two operands) no stall-free schedule exists.

For example: \( a = b; \)
\[
\begin{align*}
\text{ld} & \quad [b], \%10 \\
\text{st} & \quad \%10, \ [a]
\end{align*}
\]
Why Does the Algorithm Avoid Stalls?

Previously, certain “critical” loads had to appear just before an operation that used their value.

Now, we have an “extra” register. This allows critical loads to move up one or more places, avoiding any stalls.
How Do We Schedule Small Expressions?

Small expressions (one or two operands) are common. We’d like to avoid stalls when scheduling them.

Idea—Blend small expressions together into larger expression trees, using “,” and “;” like binary operators.
Example

\[
a = b + c; \quad d = e;
\]

\[
\begin{array}{c}
\text{Orginal Code} \\
\text{In Canonical Form} \\
\text{After Register Assignment}
\end{array}
\]

```
ld [b], PR1
ld [c], PR2
add PR1,PR2,PR3
st PR3, [a]
ld [e], PR4
st PR4, [d]
```

```
ld [b], PR1
ld [c], PR2
ld [e], PR4
add PR1,PR2,PR3
st PR3, [a]
st PR4, [d]
```

```
ld [b], %l0
ld [c], %l1
ld [e], %l2
add %l0,%l1,%l0
st %l0, [a]
st %l2, [d]
```
Global Register Allocation

Allocate registers across an entire subprogram.

A Global Register Allocator must decide:

- What values are to be placed in registers?
- Which registers are to be used?
- For how long is each Register Candidate held in a register?
**Live Ranges**

Rather than simply allocate a value to a fixed register throughout an entire subprogram, we prefer to **split** variables into **Live Ranges**.

**What is a Live Range?**

It is the span of instructions (or basic blocks) from a definition of a variable to all its uses.

Different assignments to the same variable may reach distinct & disjoint instructions or basic blocks.

If so, the live ranges are **Independent**, and may be assigned **Different** registers.
Example

```c
a = init();
for (int i = a+1; i < 1000; i++){
    b[i] = 0; }
a = f(i);
print(a);
```

The two uses of variable a comprise Independent live ranges.
Each can be allocated separately.

If we insisted on allocating variable a to a fixed register for the whole subprogram, it would conflict with the loop body, greatly reducing its chances of successful allocation.
Granulatity of Live Ranges

Live ranges can be measured in terms of individual instructions or basic blocks.

Individual instructions are more precise but basic blocks are less numerous (reducing the size of sets that need to be computed).

We'll use basic blocks to keep examples concise.

You can define basic blocks that hold only one instruction, so computation in terms of basic blocks is still fully general.
Computation of Live Ranges

First construct the Control Flow Graph (CFG) of the subprogram.

For a Basic Block b:

Let \( \text{Preds}(b) = \) the set of basic blocks that are Immediate Predecessors of \( b \) in the CFG.

Let \( \text{Succ}(b) = \) the set of basic blocks that are Immediate Successors to \( b \) in the CFG.
Control Flow Graphs

A Control Flow Graph (CFG) models possible execution paths through a program.
Nodes are basic blocks and arcs are potential transfers of control.

For example,

```c
if (a > 0)
    b = 1;
else    b = 2;
a = c + b;
```
For a Basic Block $b$ and Variable $V$:

Let $\text{DefsIn}(b) = \text{the set of basic blocks that contain definitions of } V \text{ that reach (may be used in) the beginning of Basic Block } b$.

Let $\text{DefsOut}(b) = \text{the set of basic blocks that contain definitions of } V \text{ that reach (may be used in) the end of Basic Block } b$.

If a definition of $V$ reaches $b$, then the register that holds the value of that definition must be allocated to $V$ in block $b$.

Otherwise, the register that holds the value of that definition may be used for other purposes in $b$. 
Reading Assignment

- Read George and Appel’s paper, “Iterated Register Coalescing.” (Linked from Class Web page)

- Read Larus and Hilfinger’s paper, “Register Allocation in the SPUR Lisp Compiler.”
The sets $\text{Preds}$ and $\text{Succ}$ are derived from the structure of the CFG. They are given as part of the definition of the CFG.

$\text{DefsIn}$ and $\text{DefsOut}$ must be computed, using the following rules:

1. If Basic Block $b$ contains a definition of $V$ then
   $$\text{DefsOut}(b) = \{b\}$$

2. If there is no definition to $V$ in $b$ then
   $$\text{DefsOut}(b) = \text{DefsIn}(b)$$

3. For the First Basic Block, $b_0$:
   $$\text{DefsIn}(b_0) = \emptyset$$

4. For all Other Basic Blocks
   $$\text{DefsIn}(b) = \bigcup_{p \in \text{Preds}(b)} \text{DefsOut}(p)$$
**Liveness Analysis**

Just because a definition reaches a Basic Block, $b$, does not mean it must be allocated to a register at $b$.

We also require that the definition be Live at $b$. If the definition is dead, then it will no longer be used, and register allocation is unnecessary.

For a Basic Block $b$ and Variable $V$:

$LiveIn(b) = true$ if $V$ is Live (will be used before it is redefined) at the beginning of $b$.

$LiveOut(b) = true$ if $V$ is Live (will be used before it is redefined) at the end of $b$. 
LiveIn and LiveOut are computed, using the following rules:

1. If Basic Block \( b \) has no successors then
   \[
   \text{LiveOut}(b) = \text{false}
   \]

2. For all Other Basic Blocks
   \[
   \text{LiveOut}(b) = \bigvee_{s \in \text{Succ}(b)} \text{LiveIn}(s)
   \]

3. LiveIn(b) =
   
   If \( V \) is used before it is defined in Basic Block \( b \)
   Then true
   Elsif \( V \) is defined before it is used in Basic Block \( b \)
   Then false
   Else LiveOut(b)
Merging Live Ranges

It is possible that each Basic Block that contains a definition of v creates a distinct Live Range of V.

∀ Basic Blocks, b, that contain a definition of V:

\[
\text{Range}(b) = \{b\} \cup \{k \mid b \in \text{DefsIn}(k) \& \text{LiveIn}(k)\}
\]

This rule states that the Live Range of a definition to V in Basic Block b is b plus all other Basic Blocks that the definition of V reaches and in which V is live.
If two Live Ranges overlap (have one of more Basic Blocks in common), they must share the same register too. (Why?)

Therefore,

If \( \text{Range}(b_1) \cap \text{Range}(b_2) \neq \emptyset \)

Then replace
\[
\text{Range}(b_1) \text{ and Range}(b_2)
\]
with
\[
\text{Range}(b_1) \cup \text{Range}(b_2)
\]
Example

1. \(x\)
2. \(x\)
3. 
4. \(x\)
5. \(x\)
6. \(x\)
7. \(x\)
8. 

\(x\)
The Live Ranges we Compute are

Range(1) = \{ 1 \} \cup \{ 3, 4 \} = \{ 1, 3, 4 \}

Range(2) = \{ 2 \} \cup \{ 4 \} = \{ 2, 4 \}

Range(5) = \{ 5 \} \cup \{ 7 \} = \{ 5, 7 \}

Range(6) = \{ 6 \} \cup \{ 7 \} = \{ 6, 7 \}

Ranges 1 and 2 overlap, so

Range(1) = Range(2) = \{ 1, 2, 3, 4 \}

Ranges 5 and 6 overlap, so

Range(5) = Range(6) = \{ 5, 6, 7 \}
Interference Graph

An Interference Graph represents interferences between Live Ranges.

Two Live Ranges interfere if they share one or more Basic Blocks in common.

Live Ranges that interfere must be allocated different registers.

In an Interference Graph:
- Nodes are Live Ranges
- An undirected arc connects two Live Ranges if and only if they interfere
Example

```c
int p(int lim1, int lim2) {
    for (i=0; i<lim1 && A[i]>0; i++) {
    }
    for (j=0; j<lim2 && B[j]>0; j++) {
    }
    return i+j;
}
```

We optimize array accesses by placing \&A[0] and \&B[0] in temporaries:

```c
int p(int lim1, int lim2) {
    int *T1 = &A[0];
    for (i=0; i<lim1 && *(T1+i)>0; i++) {
    }
    int *T2 = &B[0];
    for (j=0; j<lim2 && *(T2+j)>0; j++) {
    }
    return i+j;
}
```
Register Allocation via Graph Coloring

We model global register allocation as a Coloring Problem on the Interference Graph

We wish to use the fewest possible colors (registers) subject to the rule that two connected nodes can’t share the same color.
Optimal Graph Coloring is NP-Complete

Reference:

We’ll use a Heuristic Algorithm originally suggested by Chaitin et. al. and improved by Briggs et. al.

References:

“Register Allocation Via Coloring,” G. Chaitin et. al., Computer Languages, 1981.

“Improvement to Graph Coloring Register Allocation,” P. Briggs et. al., PLDI, 1989.
Coloring Heuristic

To R-Color a Graph (where R is the number of registers available)

1. While any node, n, has < R neighbors:
   Remove n from the Graph.
   Push n onto a Stack.

2. If the remaining Graph is non-empty:
   Compute the cost of each node.
   The Cost of a Node (a Live Range) is the number of extra instructions needed if the Node isn’t assigned a register, scaled by $10^{\text{loop\_depth}}$.
   Let $NB(n) =$ Number of Neighbors of n.
   Remove that node n that has the smallest $\text{Cost}(n)/NB(n)$ value.
   Push n onto a Stack.
   Return to Step 1.
3. While Stack is non-empty:
   Pop n from the Stack.
   If n’s neighbors are assigned fewer than R colors
   Then assign n any unassigned color
   Else leave n uncolored.
Example

```c
int p(int lim1, int lim2) {
    int *T1 = &A[0];
    for (i=0; i<lim1 && *(T1+i)>0; i++){}
    int *T2 = &B[0];
    for (j=0; j<lim2 && *(T2+j)>0; j++){}
    return i+j;
}
```

Do a 3 coloring

<table>
<thead>
<tr>
<th></th>
<th>lim1</th>
<th>lim2</th>
<th>T1</th>
<th>T2</th>
<th>i</th>
<th>j</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Cost</strong></td>
<td>11</td>
<td>11</td>
<td>11</td>
<td>11</td>
<td>42</td>
<td>42</td>
</tr>
<tr>
<td><strong>Cost/Neighbors</strong></td>
<td>11/3</td>
<td>11/5</td>
<td>11/3</td>
<td>11/3</td>
<td>42/5</td>
<td>42/3</td>
</tr>
</tbody>
</table>
Since no node has fewer than 3 neighbors, we remove a node based on the minimum Cost/Neighbors value.

\( \text{lim2 is chosen.} \)

We now have:

Remove (say) \( \text{lim1} \), then \( T1, T2, j \) and \( i \) (order is arbitrary).
The Stack is:

i
j
T2
T1
lim1
lim2

Assuming the colors we have are R1, R2 and R3, the register assignment we choose is

\[ i:R1, j:R2, T2:R3, T1:R2, \text{lim1}:R3, \text{lim2}:\text{spill} \]
Color Preferences

Sometimes we wish to assign a particular register (color) to a selected Live Range (e.g., a parameter or return value) if possible.

We can mark a node in the Interference Graph with a Color Preference.

When we unstack nodes and assign colors, we will avoid choosing color c if an uncolored neighbor has indicted a preference for it. If only color c is left, we take it (and ignore the preference).
Example

Assume in our previous example that lim1 has requested register R1 and lim2 has requested register R2 (because these are the registers the parameters are passed in).
Now when $i$, $j$ and $T_1$ are unstacked, they respect $\text{lim}_1$'s and $\text{lim}_2$'s preferences:

$i:R_3$, $j:R_1$, $T_2:R_2$, $T_1:R_2$, $\text{lim}_1:R_1$, $\text{lim}_2:\text{spill}$
Using Coloring to Optimize Register Moves

A nice “fringe benefit” of allocating registers via coloring is that we can often optimize away register to register moves by giving the source and target the same color.

Consider

Live in: $a, b$

$t1 = a + b$

$x = t1$

$y = x + 1$

$q = t1$

Live out: $y, q$

We’d like $x, t1$ and $q$ to get the same color. How do we “force” this?
We can “merge” $x, t_1$ and $q$ together:

Live in: $a, b$

$t_1 = a + b$

$x = t_1$

$y = x + 1$

$q = t_1$

Live out: $y, q$

Now a 2-coloring that optimizes away both register to register moves is trivial.
Reckless Coalescing

Originally, Chaitin suggested merging all move-related nodes that don’t interfere.

This is reckless—the merged node may not be colorable!

(Is it worth a spill to save a move??)

This Graph is 2-colorable before the reckless merge, but not after.
Conservative Coalescing

In response to Chaitin’s reckless coalescing approach, Briggs suggested a more conservative approach.

See “Improvement to Graph Coloring Register Allocation,” P. Briggs et. al., ACM Toplas, May 1994.
Briggs suggested that two move-related nodes should be merged only if the combined source and target node has fewer than R neighbors.

This guarantees that the combined node will be colorable, but may miss some optimization opportunities.

After a merge of nodes a and d, there will be four neighbors, but a 2-coloring is still possible.
Iterated Coalescing

This is an intermediate approach, that seeks to be safer than reckless coalescing and more effective than conservative coalescing. It was proposed by George and Appel.
1. Build:
   Create an Interference Graph, as usual. Mark source-target pairs with a special move-related arc (denoted as a dashed line).

2. Simplify:
   Remove and stack non-move-related nodes with < R neighbors.

3. Coalesce:
   Combine move-related pairs that will have < R neighbors after coalescing.

Repeat steps 2 and 3 until only nodes with R or more neighbors or move-related nodes remain or the graph is empty.
4. Freeze:

If the Interference Graph is non-empty:
Then If there exists a move-related node with $< R$ neighbors
Then: “Freeze in” the move and make the node non-move-related.
Return to Steps 2 and 3.
Else: Use Chaitin’s Cost/Neighbors criterion to remove and stack a node.
Return to Steps 2 and 3.

5. Unstack:

Color nodes as they are unstacked as per Chaitin and Briggs.
Example

Live in: k, j
g = mem[j+12]
h = k-1
f = g*h
e = mem[j+8]
m = mem[j+16]
b = mem[f]
c = e+8
d = c
k = m+4
j = b
goto d
Live out: d, k, j

Assume we want a 4-coloring.
Note that neither j & b nor d & c can be conservatively colored.
We simplify by removing nodes with fewer than 4 neighbors.

We remove and stack: g, h, k, f, e, m
The remaining Interference Graph is

We can now conservatively coalesce the move-related pairs to obtain

These remaining nodes can now be removed and stacked.
We can now unstack and color:

d&c: R1, j&b: R2, m: R3, e: R4, f: R1, k: R3, h: R1, g: R4

No spills were required and both moves were optimized away.
Reading Assignment

- Read David Wall’s paper, “Global Register Allocation at Link Time.”
Priority-Based Register Allocation

Alternatives to Chaitin-style register allocation are presented in:

These papers suggest two innovations:

1. **Use of a Priority Value to choose nodes to color in an Interference Graph.**

   A Priority measures
   
   \[
   \text{(Spill cost)}/(\text{Size of Live Range})
   \]

   The idea is that small live ranges with a high spill cost are ideal candidates for register allocation. As the size of a live range grows, it becomes less attractive for register allocation (since it “ties up” a register for a larger portion of a program).

2. **Live Range Splitting**

   Rather than spill an entire live range that can’t be colored, the live range is split into two or more smaller live ranges that may be colorable.
Large vs. Small Live Ranges

- A large live range has less spill code. Values are directly read from and written to a register. But, a large live range is harder to allocate, since it may conflict with many other register candidates.

- A small live range is easier to allocate since it competes with fewer register candidates. But, more spill code is needed to load and save register values across live ranges.

- In the limit a live range can shrink to a single definition or use of a register. But, then we really don’t have an effective register allocation at all!
Terminology

In an Interference Graph:

- A node with fewer neighbors than colors is termed **unconstrained**. It is trivial to color.

- A node that is not unconstrained is termed **constrained**. It may need to be split or spilled.
PriorityRegAlloc(proc, regCount) {
    ig ← buildInterferenceGraph(proc)
    unconstrained ←
        \{ n ∈ nodes(ig) \mid neighborCount(n) < regCount \}
    constrained ←
        \{ n ∈ nodes(ig) \mid neighborCount(n) ≥ regCount \}

    while( constrained ≠ φ ) {
        for ( c ∈ constrained such that not colorable(c) and canSplit(c) ) {
            c1, c2 ← split(c)
            constrained ← constrained - \{c\}
            if ( neighborCount(c1) < regCount )
                unconstrained ← unconstrained U \{ c1\}
            else constrained ← constrained U \{ c1\}
            if ( neighborCount(c2) < regCount )
                unconstrained ← unconstrained U \{ c2\}
            else constrained ← constrained U \{ c2\}
            for ( d ∈ neighbors(c) such that
d ∈ unconstrained and
                neighborCount(d) ≥ regCount ){
                unconstrained ← unconstrained - \{d\}
                constrained ← constrained U \{d\}
            } // End of both for loops
        } // End of while
    } // End of while
/ At this point all nodes in constrained are colorable or can’t be split */

Select p ∈ constrained such that priority(p) is maximized
if ( colorable(p) )
    color(p)
else  spill(p)
} // End of While

color all nodes ∈ unconstrained
}
How to Split a Constrained Node

- There are many possible partitions of a live range; too many to fully explore.
- Heuristics are used instead. One simple heuristic is:

  1. Remove the first basic block (or instruction) of the live range. Put it into a new live range, NR.

  2. Move successor blocks (or instructions) from the original live range into NR, as long as NR remains colorable.

  3. Single Basic Blocks (or instructions) that can’t be colored are spilled.
Example

```c
int sum(int a[], int b[]) {
    int sum = 0;
    for (int i=0; i<1000; i++)
        sum += a[i];
    for (int j=0; j<1000; j++)
        sum += b[j];
    return sum;
}
```

Assume we want a 3-coloring.
We first simplify the graph by removing unconstrained nodes (those with < 3 neighbors).

Node $j$ is removed. We now have:

At this point, each node has 3 neighbors, so either spilling or splitting is necessary.

A spill really isn’t attractive as each of the 4 register candidates is used within a loop, magnifying the costs of accessing memory.
**Coloring by Priorities**

We’ll color constrained nodes by priority values, with preference given to large priority values.
1. \( a = \text{parm1} \)  
   \( b = \text{parm2} \)  
   \( \text{sum} = 0 \)  
   \( i = 0 \)

2. \( i < 1000 \)

3. \( \text{sum} += a[i] \)  
   \( i++ \)

4. \( j = 0 \)

5. \( j < 1000 \)

6. \( \text{sum} += b[j] \)  
   \( j++ \)

7. \( \text{return sum} \)

<table>
<thead>
<tr>
<th></th>
<th>a</th>
<th>b</th>
<th>sum</th>
<th>i</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cost</td>
<td>11</td>
<td>11</td>
<td>42</td>
<td>41</td>
</tr>
<tr>
<td>Cost/Size</td>
<td>11/3</td>
<td>11/6</td>
<td>42/7</td>
<td>41/3</td>
</tr>
</tbody>
</table>
Variables \( i \), \( \text{sum} \) and \( a \) are assigned colors \( R_1 \), \( R_2 \) and \( R_3 \).

Variable \( b \) can’t be colored, so we will try to split it. \( b \)’s live range is blocks 1 to 6, with 1 as \( b \)’s entry point.

Blocks 1 to 3 can’t be colored, so \( b \) is spilled in block 1. However, blocks 4 to 6 form a split live range that can be colored (using \( R_3 \)).

We will reload \( b \) into \( R_3 \) in block 4, and it will be register-allocated throughout the second loop. The added cost due to the split is minor—a store in block 1 and a reload in block 4.
Interprocedural Register Allocation

The goal of register allocation is to keep frequently used values in registers.

Ideally, we’d like to go to memory only to access values that may be aliased or pointed to.

For example, array elements and heap objects are routinely loaded from and stored to memory each time they are accessed.
With alias analysis, optimizations like Scalarization are possible.

```
for (i=0; i<1000; i++)
    for (j=0; j<1000; j++)
        a[i] += i * b[j];
```

is optimized to

```
for (i=0; i<1000; i++){
    int Ai = a[i];
    for (j=0; j<1000; j++)
        Ai += i * b[j];
    a[i] = Ai;
}
```
Reading Assignment

• Read “Minimum Cost Interprocedural Register Allocation,” by S. Kurlander et al. (linked from class Web page).

• Get Handout #4 from Dolt.
Attacking Call Overhead

- Even with good global register allocation calls are still a problem.
- In general, the caller and callee may use the same registers, requiring saves and restores across calls.
- Register windows help, but they are inflexible, forcing all subprograms to use the same number of registers.
- We’d prefer a register allocator that is sensitive to the calling structure of a program.
Call Graphs

A Call Graph represents the calling structure of a program.

- Nodes are subprograms (procedures and functions).
- Arcs represent calls between subprograms. An arc from A to B denotes that a call to B appears within A.
- For an indirect call (a function parameter or a function pointer) an arc is added to all potential callees.
Example

main() {
    if (pred(a, b)
        subr1(a)
    else subr2(b);}

bool pred(int a, int b){
    return a==b; }

subr1(int a) { print(a);}

subr2(int x) { print(2*x);}

main
    pred
    subr1
    subr2
        print
Wall’s Interprocedural Register Allocator

Operates in two phases:

1. Register candidates are identified at the subprogram level. Each candidate (a single variable or a set of non-interfering live ranges) is compiled as if it won’t get a register. At link-time unnecessary loads and stores are edited away if the candidate is allocated a register.

2. At link-time, when all subprograms are known and available, register candidates are allocated registers.
Identifying Interprocedural Register Sharing

If two subprograms are not connected in the call graph, a register candidate in each can share the same register without any saving or restoring across calls.

A register candidate from `pred`, `subr1` and `subr2` can all share one register.
At the interprocedural level we must answer 2 questions:

1. A local candidate of one subprogram can share a register with candidates of what other subprograms?

2. Which local register candidates will yield the greatest benefit if given a register?

Wall designed his allocator for a machine with 52 registers. This is enough to divide all the registers among the subprograms without any saves or restores at call sites.

With fewer registers, spills, saves and restores will often be needed (if registers are used aggressively within a subprogram).
Restrictions on the Call Graph

Wall limited calls graphs to DAGs since cycles in a call graph imply recursion, which will force saves and restores (why?)

Cost Computations

Each register candidate is given a per-call cost, based on the number of saves and restores that can be removed, scaled by $10^{\text{loop_depth}}$. This benefit is then multiplied by the expected number of calls, obtained by summing the total number of call sites, scaled by loop nesting depth.
Grouping Register Candidates

We now have an estimate of the benefit of allocating a register to a candidate. Call this estimate cost(candidate).

We estimate potential interprocedural sharing of register candidates by assigning each candidate to a Group.

All candidates within a group can share a register. No two candidates in any subprogram are in the same group.
Groups are assigned during a reverse depth-first traversal of the call graph.

AsgGroup(node n) {
    if (n is a leaf node)
        grp = 0
    else {
        for (each c ∈ children(n)) {
            AsgGroup(c)
        }
        grp = 1 + Max (Max group used in c)
        c ∈ children(n)
    }
    for (each r ∈ registerCandidates(n)) {
        assign r to grp
        grp++
    }
}

Global variables are assigned to a singleton group.
Example

At Print: grp(i)=0, grp(j)=1
At subr1: Max grp used in print is 1
  grp(x)=2, grp(y)=3
At subr2: Max grp used in print is 1
  grp(t)=2
At main: Max grp used in children is 3
  grp(a)=4, grp(b)=5, grp(c)=6
If A calls B (directly or indirectly), then none of A’s register candidates are in the same group as any of B’s register candidates.

This guarantees that A and B will use different registers.

Thus no saves or restores are needed across a call from A to B.
Assigning Registers to Groups

Cost(group) = \sum_{\text{candidates} \in \text{group}} \text{cost(candidates)}

We assign registers to groups based on the cost of each group, using an “auction.”

for (r=0; r < RegisterCount; r++) {
    Let G be the group with the greatest cost that has not yet been assigned a register.
    Assign r to G
}

Example (3 Registers)

<table>
<thead>
<tr>
<th>Group</th>
<th>Members</th>
<th>Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>i</td>
<td>40</td>
</tr>
<tr>
<td>1</td>
<td>j</td>
<td>5</td>
</tr>
<tr>
<td>2</td>
<td>x, t</td>
<td>15</td>
</tr>
<tr>
<td>3</td>
<td>y</td>
<td>15</td>
</tr>
<tr>
<td>4</td>
<td>a</td>
<td>20</td>
</tr>
<tr>
<td>5</td>
<td>b</td>
<td>10</td>
</tr>
<tr>
<td>6</td>
<td>c</td>
<td>30</td>
</tr>
</tbody>
</table>
The 3 registers are given to the groups with the highest weight, i (40), c(30), a(20).
Is this optimal?
No! If y and t are grouped together, y and t (cost=25) get the last register.
**Recursion**

To handle recursion, any call to a subprogram “up” in the call graph must save and restore all registers possibly in use between the caller and callee.

A call from E to B saves r3 to r5.
Performance

Wall found interprocedural register allocation to be very effective (given 52 Registers!).

Speedups of 10-28% were reported. Even with only 8 registers, speedups of 5-20% were observed.
Optimal Interprocedural Register Allocation

Wall’s approach to interprocedural register allocation isn’t optimal because register candidates aren’t grouped to achieve maximum benefit.

Moreover, the placement of save and restore code if needed isn’t considered.

These limitations are addressed by Kurlander in “Minimum Cost Interprocedural Register Allocation.”
Optimal Save-Free Interprocedural Register Allocation

- Allocation is done on a cycle-free call graph.
- Each subprogram has one or more register candidates, $c_i$.
- Each register candidate, $c_i$, has a cost (or benefit), $w_i$, that is the improvement in performance if $c_i$ is given a register. (This $w_i$ value is scaled to include nested loops and expected call frequencies.)
Interference Between Register Candidates

The notion of interference is extended to include interprocedural register candidates:

- Two Candidates in the same subprogram always interfere. (Local non-interfering variables and values have already been grouped into interprocedural register candidates.)

- If subprogram P calls subprogram Q (directly or indirectly) then register candidates within P always interfere with register candidates within Q.
The algorithm can group candidate p with either t or u (since they don’t interfere). It can also group candidate q with either t or u.

If two registers are available, it must “discover” that assigning R1 to q&t, and R2 to m is optimal.
Reading Assignment

• Read Section 15.4 (Code Scheduling) of Chapter 15.

• Read Gibbon’s and Muchnick’s paper, “Efficient Instruction Scheduling for a Pipelined Architecture.”

• Read Kerns and Eggers’ paper, “Balanced Scheduling: Instruction Scheduling When Memory Latency is Uncertain.” (Linked from the class Web page.)
Non-interfering register candidates are grouped into registers so as to solve:

\[
\text{Maximize } \sum_{k} w_{j} \\
\quad c_{j} \in \bigcup_{i=1}^{k} R_{i}
\]

That is, we wish to group sets of non-interfering register candidates into \( k \) registers such that the overall benefit is maximized.

But how do we solve this?

Certainly examining all possible groupings will be prohibitively expensive!
Kurlander solved this problem by mapping it to a known problem in Integer Programming: the Dual Network Flow Problem.

Solution techniques for this problem are well known—libraries of standard solution algorithms exist.

Moreover, this problem can be solved in polynomial time.

That is, it is “easier” than optimal global (intraprocedural) register allocation, which is np-complete!
Adding Saves & Restores

Wall designed his save-free interprocedural allocator for a machine with 52 registers.

Most computers have far fewer registers, and hence saving and restoring across calls, when profitable, should be allowed.

Kurlander’s Technique can be extended to include save/restore costs. If the cost of saving and restoring is less than the benefit of allocating an extra register, saving is done. Moreover, saving is done where it is cheapest (not closest!).
Example

```c
main() { ... p(); ...}

p(){ ...
    for (i=0; i<1000000; i++){
        q():
    }
}
```

We first allocate registers in a save-free mode. After all Registers have been allocated, `q` may need additional registers.

Most allocators would add save/restore code at `q`’s call site (or `q`’s prologue and epilogue).

An optimal allocator will place save/restore code at `p`’s call site, freeing a register that `p` doesn’t even want (but that `q` does want!)
Extending the Cost Model

- As before, we group register candidates of different subprograms into registers.
- Now only candidates within the same subprogram automatically interfere.
- Saves are placed on the edges of the call graph.
- We aim to solve

\[
\text{Maximize } \sum_{j} w_j \cdot c_j - \sum_{m} S_m \cdot \text{Saved}_m \quad \text{where } S_m \text{ is the per/register save/restore cost and } \text{Saved}_m \text{ is the number of registers saved on edge } e_m.
\]
• As registers are saved, they may be reused in child subprograms.

• This optimization problem can be solved as a Network Dual Flow Problem.

• Again, the solution algorithm is polynomial.
Example (One Register)

\[ \ \]

P₁ gets R₁ save-free for m.

A save on P₁ → P₄ costs 1 and gives a register to n (net profit = 2), so we do it.

A save on P₁ → P₂ for z costs 2, and yields 1, which isn’t profitable.

A save on P₂ → P₃ for q costs 4, and yields 3, which isn’t profitable.

A save on P₁ → P₂ for q costs 2, and yields 3, which is a net gain.
Handling Global Variables

- Wall’s technique handled globals by assuming they interfere with all subprograms and all other globals.

- Kurlander’s approach is incremental (and non-optimal):
  
  First, an optimal allocation for \( r \) registers is computed.

  Next, one register is “stolen” and assigned interprocedurally to the most beneficial global. (Subprograms that don’t use the global can save and restore it locally, allowing local reuse).

  An optimal allocation using \( R-1 \) registers is computed. If this solution plus the shared global is more profitable than the \( R \) register
solution, the global allocation is “locked in.”

Next, another register is “stolen” for a global, leaving R-2 for interprocedural allocation.

This process continues until stealing another register for a global isn’t profitable.
Why is Optimal Interprocedural Register Allocation Easier than Optimal Intraprocedural Allocation?

This result seems counter-intuitive. How can allocating a whole program be easier (computationally) than allocating only one subprogram.

Two observations provide the answer:

- Interprocedural allocation assumes some form of local allocation has occurred (to identify register candidates).
- Interprocedural interference is transitive (if A interferes with B and B interferes with C then A interferes with B). But intraprocedural interference isn’t transitive!
Code Scheduling

Modern processors are pipelined. They give the impression that all instructions take unit time by executing instructions in stages (steps), as if on an assembly line.

Certain instructions though (loads, floating point divides and square roots, delayed branches) take more than one cycle to execute.

These instructions may stall (halt the processor) or require a nop (null operation) to execute properly.

A Code Scheduling phase may be needed in a compiler to avoid stalls or eliminate nops.
Scheduling Expression DAGs

After generating code for a DAG or basic block, we may wish to schedule (reorder) instructions to reduce or eliminate stalls.

A Postpass Scheduler is run after code selection and register allocation.

Postpass schedulers are very general and flexible, since they can be used with code generated by any compiler with any degree of optimization.

But, since they can’t modify register allocations, they can’t always avoid stalls.
Dependency DAGs

Obviously, not all reorderings of generated instructions are acceptable.

Computation of a register value must precede all uses of that value.
A store of a value must precede all loads that might read that value.

A Dependency Dag reflects essential ordering constraints among instructions:

- Nodes are Instructions to be scheduled.
- An arc from Instruction i to Instruction j indicates that i must be executed before j may be executed.
Kinds of Dependencies

We can identify several kinds of dependencies:

- True Dependence:
  
  An operation that uses a value has a true dependence (also called a flow dependence) upon an earlier operation that computes the value. For example:
  
  \[
  \begin{align*}
  \text{mov} & \quad 1, \quad %l2 \\
  \text{add} & \quad %l2, \quad 1, \quad %l2
  \end{align*}
  \]

- Anti Dependence:
  
  An operation that writes a value has an anti dependence upon an earlier operation that reads the value. For example:
  
  \[
  \begin{align*}
  \text{add} & \quad %l2, \quad 1, \quad %l0 \\
  \text{mov} & \quad 1, \quad %l2
  \end{align*}
  \]
• Output Dependence:

An operation that writes a value has an output dependence upon an earlier operation that writes the value. For example:

```
mov  1, %l2
mov  2, %l2
```

Collectively, true, anti and output dependencies are called data dependencies. Data dependencies constrain the order in which instructions may be executed.
Example

Consider the code that might be generated for

\[ a = ((a+b) + (c*d)) + ((c+d) * d); \]

We’ll assume 4 registers, the minimum possible, and we’ll reuse already loaded values.

Assume a 1 cycle stall between a load and use of the loaded value and a 2 cycle stall between a multiplication and first use of the product.
1. ld [a], %r1
2. ld [b], %r2
3. add %r1, %r2, %r1
Stall
4. ld [c], %r2
5. ld [d], %r3
Stall
6. smul %r2, %r3, %r4
Stall
7. add %r1, %r4, %r1
Stall*2
8. add %r2, %r3, %r2
9. smul %r2, %r3, %r2
Stall*2
10. add %r1, %r2, %r1
Stall*2
11. st %r1, [a]  (6 Stalls Total)
Scheduling Requires Topological Traversal

Any valid code schedule is a Topological Sort of the dependency dag.

To create a code schedule you
(1) Pick any root of the Dag.
(2) Remove it from the Dag and schedule it.
(3) Iterate!

Choosing a Minimum Delay schedule is NP-Complete:

Dynamically Scheduled (Out of Order) Processors

To avoid stalls, some processors can execute instructions Out of Program Order.

If an instruction can’t execute because a previous instruction it depends upon hasn’t completed yet, the instruction can be “held” and a successor instruction executed instead.

When needed predecessors have completed, the held instruction is released for execution.
Example

1. `ld [a], %r1`
2. `ld [b], %r2`
3. `add %r1, %r2, %r1`
4. `ld [c], %r2`
5. `ld [d], %r3`
6. `smul %r2, %r3, %r4`
7. `add %r1, %r4, %r1`
8. `add %r2, %r3, %r2`
9. `smul %r2, %r3, %r2`
10. `add %r1, %r2, %r1`
11. `st %r1, [a]` (2 Stalls Total)
Limitations of Dynamic Scheduling

1. Extra processor complexity.

2. Register renaming (to avoid False Dependencies) may be needed.

3. Identifying instructions to be delayed takes time.

4. Instructions “late” in the program can’t be started earlier.
Reading Assignment

- Read Goodman and Hsu’s paper, “Code Scheduling and Register Allocation in Large Basic Blocks.”
- Read Bernstein and Rodeh’s paper, “Global Instruction Scheduling for Superscalar Machines.” (Linked from the class Web page.)
Gibbons & Muchnick Postpass Code Scheduler

1. If there is only one root, schedule it.

2. If there is more than one root, choose that root that won’t be stalled by instructions already scheduled.

3. If more than one root can be scheduled without stalling, consider the following rules (in order);
   (a) Does this root stall any of its successors? (If so, schedule it immediately.)
   (b) How many new roots are exposed if this node is scheduled? (More is better.)
(c) Which root has the longest weighted path to a leaf (using instruction delays as the weight). (The “critical path” in the DAG gets priority.)
Example

1. `ld [a], %r1` //Longest path
2. `ld [b], %r2` //Exposes a root
3. `add %r1,%r2,%r1` //Only choice
4. `ld [c], %r2` //Only choice
5. `ld [d], %r3` //Not delayed
6. `smul %r2,%r3,%r4` //Stalls succ.
7. `add %r1,%r4,%r1` //Only choice
8. `add %r2,%r3,%r2` //Not delayed
9. `smul %r2,%r3,%r2` //Not delayed
10. `add %r1,%r2,%r1` //Only choice
11. `st %r1,[a]` (2 Stalls Total)
False Dependencies

We still have delays in the schedule that was produced because of “false dependencies.”

Both b and c are loaded into %r2. This limits the ability to move the load of c prior to any use of %r2 that uses b.

To improve our schedule we can use a processor that renames registers or allocate additional registers to remove false dependencies.
Register Renaming

Many out of order processors automatically rename distinct uses of the same architectural register to distinct internal registers.

Thus

\[
\begin{align*}
\text{ld} & \ [a],\%r1 \\
\text{ld} & \ [b],\%r2 \\
\text{add} & \ %r1,%r2,%r1 \\
\text{ld} & \ [c],\%r2 \\
\end{align*}
\]

is executed as if it were

\[
\begin{align*}
\text{ld} & \ [a],\%r1 \\
\text{ld} & \ [b],\%r2 \\
\text{add} & \ %r1,%r2,%r3 \\
\text{ld} & \ [c],\%r4 \\
\end{align*}
\]

Now the final load can be executed prior to the add, eliminating a stall.
Compiler Renaming

A compiler can also use the idea of renaming to avoid unnecessary stalls. An extra register may be needed (as was the case for scheduling expression trees).

Also, a round-robin allocation policy is needed. Registers are reused in a cyclic fashion, so that the most recently freed register is reused last, not first.
Example

1. ld [a], %r1
2. ld [b], %r2
3. add %r1,%r2,%r1
4. ld [c], %r3
5. ld [d], %r4
6. smul %r3,%r4,%r5
7. add %r1,%r5,%r2
8. add %r3,%r4,%r3
9. smul %r3,%r4,%r3
10. add %r2,%r3,%r2
11. st %r2,[a] (6 Stalls Total)
After Scheduling:

4. `ld [c], %r3` //Longest path
5. `ld [d], %r4` //Exposes a root
1. `ld [a], %r1` //Stalls succ.
2. `ld [b], %r2` //Exposes a root
6. `smul %r3,%r4,%r5` //Stalls succ.
8. `add %r3,%r4,%r3` //Longest path
9. `smul %r3,%r4,%r3` //Stalls succ.
3. `add %r1,%r2,%r1` //Only choice
7. `add %r1,%r5,%r2` //Only choice
10. `add %r2,%r3,%r2` //Only choice
11. `st %r2,[a]` (0 Stalls Total)
Balanced Scheduling

When scheduling a load, we normally anticipate the best case, a hit in the primary cache.

On older architectures this makes sense, since we stall execution on a cache miss.

Many newer architectures are non-blocking. This means we can continue execution after a miss until the loaded value is used.

Assume a Cache miss takes $N$ cycles ($N$ is typically 10 or more).

Do we schedule a load anticipating a 1 cycle delay (a hit) or an $N$ cycle delay (a miss)?
Neither Optimistic Scheduling (expect a hit) nor Pessimistic Scheduling (expect a miss) is always better.

Consider

An Optimistic Schedule is
load Inst1 Inst2
  
Inst3 Inst4

Fine for a hit; inferior for a miss.

A Pessimistic Schedule is
load Inst2 Inst3 Inst4
  
Inst1

Fine for a hit; better for a miss.
But things become more complex with multiple loads

An Optimistic Schedule is

A Pessimistic Schedule is

Better for hits; same for misses.

Worse for hits; same for misses.
Eggers suggests a balanced scheduler that spaces out loads, using available independent instructions as “filler.” The insight is that scheduling should not be driven by worst-case latencies but rather by available independent instructions.

For

it produces

<table>
<thead>
<tr>
<th>load</th>
<th>Inst1</th>
<th>Inst2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Inst3</td>
<td>Inst4</td>
<td></td>
</tr>
</tbody>
</table>

Good; maximum distance between load and Inst1 in case of a miss.
balanced scheduling produces

load1  Inst1
load2  Inst2
Inst3

Good for hits; as good as possible for misses.
**Idea of the Algorithm**

Look at each Instruction, $i$, in the Dependency DAG.

Determine which loads can run in parallel with $i$ and use all (or part) of $i$’s execution time to cover the latency of these loads.
Compute available latency of each load:
Give each load instruction an initial latency of 1.
For (each instruction i in the Dependency DAG) do:
  Consider Instructions Independent of i:
  \[ G_{\text{ind}} = \text{DepDAG} - (\text{AllPred}(i) \cup \text{AllSucc}(i) \cup \{i\}) \]
  For (each connected subgraph c in \( G_{\text{ind}} \)) do:
    Find \( m = \) maximum number of load instructions on any path in c.
    For (each load d in c) do:
      add \( 1/m \) to d’s latency.
Computing the Schedule Using Adjusted Latencies

Once latencies are assigned to each load (other instructions have a latency of 1), we annotate each instruction in the Dependency DAG with its critical path weight: the maximum latency (along any path) from the instruction to a Leaf of the DAG.

Instructions are scheduled using critical path values; the root with the highest critical path value is always scheduled next. In cases of ties (same critical path value), operations with the longest latency are scheduled first.
Example

<table>
<thead>
<tr>
<th>Load</th>
<th>Ld 1</th>
<th>Ld 2</th>
<th>Ld 3</th>
<th>Ld 4</th>
<th>I1</th>
<th>I2</th>
<th>I3</th>
<th>I4</th>
<th>I5</th>
<th>Latency</th>
</tr>
</thead>
<tbody>
<tr>
<td>Load1</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>1</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>1+0 = 1</td>
</tr>
<tr>
<td>Load2</td>
<td></td>
<td>1/2</td>
<td>1/2</td>
<td>1/2</td>
<td>1/2</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>1+2 = 3</td>
</tr>
<tr>
<td>Load3</td>
<td></td>
<td>1/2</td>
<td>1/2</td>
<td>1/2</td>
<td>1/2</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>1+2 = 3</td>
</tr>
<tr>
<td>Load4</td>
<td>1</td>
<td>1</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>1</td>
<td>1+3 = 4</td>
</tr>
</tbody>
</table>
Using the annotated Dependency Dag, instructions can be scheduled:

- Load1
- Inst1
- Load2
- Inst2
- Inst3
- Load4
- Inst4
- Inst5
- End

- Load1: (0 latency; unavoidable)
- Inst1: (3 instruction latency)
- Load2: (2 instruction latency)
- Inst2: (1 instruction latency)
Goodman/Hsu Integrated Code Scheduler

Prepass Schedulers:
Schedule code prior to register allocation.
Can overuse registers—Always using a “fresh” register maximizes freedom to rearrange Instructions.

Postpass Schedulers:
Schedule code after register allocation.
Can be limited by “false dependencies” induced by register reuse.
Example is Gibbons/Muchnick heuristic.
Integrated Schedulers

Capture best of both approaches.

When registers are plentiful, use additional registers to avoid stalls. Goodman & Hsu call this CSP: Code Scheduling for Pipelines.

When registers are scarce, switch to a policy that frees registers. Goodman & Hsu call this CSR: Code Scheduling to free Registers.
Assume code is generated in single assignment form, with a unique pseudo-register for each computed value.

We schedule from a DAG where nodes are operations (to be mapped to instructions), and arcs represent data dependencies.

Each node will have an associated Cost, that measures the execution and stall time of the instruction that the node represents.

Nodes are labeled with a critical path cost, used to select the “most critical” instructions to schedule.
Definitions

Leader Set:
Set of DAG nodes ready to be scheduled, possibly with an interlock.

Ready Set:
Subset of Leader Set; Nodes ready to be scheduled without an interlock.

AvailReg:
A count of currently unused registers.

MinThreshold:
Threshold at which heuristic will switch from avoiding interlocks to reducing registers in use.
Goodman/Hsu Heuristic:

while (DAG ≠ φ) {
    if (AvailReg > MinThreshold)
        if (ReadySet ≠ φ)
            Select Ready node with Max cost
        else Select Leader node with Max cost
    else // Reduce Registers in Use
        if (∃ node ∈ ReadySet that frees registers) {
            Select node that frees most registers
            If (selected node isn’t unique)
                Select node with Max cost
        } elseif (∃ node ∈ LeaderSet that frees regs) {
            Select node that frees most registers
            If (selected node isn’t unique)
                Select node with fewest interlocks
        } else find a partially evaluated path and
            select a leader from this path
        else Select any node in ReadySet
        else Select any node in LeaderSet
    Schedule Selected node
    Update AvailReg count   }//end while
Example

We’ll again consider

\[ a = (((a+b) + (c*d)) + ((c+d) * d)); \]

Again, assume a 1 cycle stall between a load and use of its value and a 2 cycle stall between a multiplication and first use of the product.
We’ll try 4 registers (the minimum), then 5 registers.

Should MinThreshold be 0 or 1?

At MinThreshold = 1, we always have a register to hold a result, but we may force a register to be spilled too soon!

At MinThreshold = 0, we may be forced to spill a register to free a result register.

But, we’ll also be able to schedule more aggressively.

Is a spill or stall worse?

Note that we may be able to “hide” a spill in a delay slot!

We’ll be aggressive and use MinThreshold = 0.
4 Registers Used (1 Stall)

Scheduling for Superscalar & Multiple Issue Machines

A number of computers have the ability to issue more than one instruction per cycle if the instructions are independent and satisfy constraints on available functional units.

Thus the instructions

\[
\begin{align*}
\text{add} & \ %r1,1,%r2 \\
\text{sub} & \ %r1,2,%r3
\end{align*}
\]

can issue and execute in parallel, but

\[
\begin{align*}
\text{add} & \ %r1,1,%r2 \\
\text{sub} & \ %r2,2,%r3
\end{align*}
\]

must execute sequentially.
Instructions that are linked by true or output dependencies must execute sequentially, but instructions that are linked by an anti dependence may execute concurrently.

For example,

\[
\begin{align*}
\text{add } & \%r1, 1, \%r2 \\
\text{sub } & \%r3, 2, \%r1
\end{align*}
\]

can issue and execute in parallel.

The code scheduling techniques we've studied can be used to schedule machines that can issue 2 or more independent instructions simultaneously.

We select pairs (or triples or n-tuples), verifying (with the Dependence Dag) that they are independent or anti dependent.
Example: 5 Registers (2 Wide Issue)

We need only 8 cycles rather than 11.

<table>

</table>
5 Registers (3 Wide Issue)

We still need 8 cycles!
Finding Additional Independent Instructions for Parallel Issue

We can extend the capabilities of processors:

- Out of order execution allows a processor to “search ahead” for independent instructions to launch.

- But, since basic blocks are often quite small, the processor may need to accurately predict branches, issuing instructions before the execution path is fully resolved.

- But, since branch predictions may be wrong, it will be necessary to “undo” instructions executed speculatively.
Compiler Support for Extended Scheduling

- Trace Scheduling
  Gather sequences of basic blocks together and schedule them as a unit.

- Global Scheduling
  Analyze the control flow graph and move instructions across basic block boundaries to improve scheduling.

- Software Pipelining
  Select instructions from several loop iterations and schedule them together.
Trace Scheduling

Reference:

Idea:
Since basic blocks are often too small to allow effective code scheduling, we will profile a program’s execution and identify the most frequently executed paths in a program.

Sequences of contiguous basic blocks on frequently executed paths will be gathered together into traces.
Trace

- A sequence of basic blocks (excluding loops) executed together can form a trace.
- A trace will be scheduled as a unit, allowing a larger span of instructions for scheduling.
- A loop can be unrolled or scheduled individually.
- Compensation code may need to be added when a branch into, or out of, a trace occurs.
Assume profiling shows that
$B1 \rightarrow B3 \rightarrow B4^+ \rightarrow B5 \rightarrow B7$
is the most common execution path.
The traces extracted from this path are
$B1 \rightarrow B3$, $B4$, and $B5 \rightarrow B7$. 
Compensation Code

When we move instructions across basic block boundaries within a trace, we may need to add extra instructions that preserve program semantics on paths that enter or leave the trace.
Example

In the previous example, basic block B1 had B2 and B3 as successors, and B1 → B3 formed a trace.

Before Scheduling

1. \(x = x + 1\)
   \(y = x - y\)
   \(x < 5\)

2. \(z = x \times z\)
   \(x = x + 1\)

3. \(y = 2 \times y\)
   \(x = x - 2\)

After Scheduling

1. \(x = x + 1\)
   \(x < 5\)

2. \(y = x - y\)
   \(z = x \times z\)
   \(x = x + 1\)

3. \(y = x - y\)
   \(y = 2 \times y\)
   \(x = x - 2\)
Advantages & Disadvantages

- Trace scheduling allows scheduling to span multiple basic blocks. This can significantly increase the effectiveness of scheduling, especially in the context of superscalar processors (which need ILP to be effective).

- Trace Scheduling can also increase code size (because of compensation code). It is also sensitive to the accuracy of trace estimates.
Reading Assignment

• Read pp 367-386 of Allan et. al.'s paper, “Software Pipelining.” (Linked from the class Web page.)
Global Code Scheduling

- Bernstein and Rodeh approach.
- A prepass scheduler (does scheduling before register allocation).
- Can move instructions across basic block boundaries.
- Prefers to move instructions that must eventually be executed.
- Can move Instructions speculatively, possibly executing instructions unnecessarily.
Data & Control Dependencies

When moving instructions across basic block boundaries, we must respect both data dependencies and control dependencies.

Data dependencies specify necessary orderings among instructions that produce a value and instructions that use that value.

Control dependencies determine when (and if) various instructions are executed. Thus an instruction is control dependent on expressions that affect flow of control to that instruction.
Definitions used in Global Scheduling

- Basic Block $A$ dominates Basic Block $B$ if and only if $A$ appears on all paths to $B$.

- Basic Block $B$ postdominates Basic Block $A$ if and only if $B$ appears on all paths from $A$ to an exit point.

- Basic Blocks $A$ and $B$ are equivalent if and only if $A$ dominates $B$ and $B$ postdominates $A$.

- Moving an Instruction from Basic Block $B$ to Basic Block $A$ is useful if and only if $A$ and $B$ are equivalent.

- Moving an Instruction from Basic Block $B$ to Basic Block $A$ is speculative if $B$ does not postdominate $A$. 
• Moving an Instruction from Basic Block B to Basic Block A requires duplication if A does not dominate B.

We prefer a move that does not require duplication. (Why?)

The degree of speculation in moving an instruction from one basic block to another can be quantified:

• Moving an Instruction from Basic Block B to Basic Block A is \( n \)-branch speculative if \( n \) conditional branches occur on a path from A to B.
Example

d = a + b;
if ( d != 0)
    flag = 1;
else flag = 0;
f = d - g;

Blocks 1 and 4 are equivalent.
Moving an Instruction from B2 to B1 (or B3 to B1) is 1-branch speculative.
Moving an Instruction from B4 to B2 (or B4 to B3) requires duplication.
Limits on Code Motion

Assume that pseudo registers are used in generated code (prior to register allocation).

To respect data dependencies:

- A use of a Pseudo Register can’t be moved above its definition.
- Memory loads can’t be moved ahead of Stores to the same location.
- Stores can’t be moved ahead of either loads or stores to the same location.
- A load of a memory location can be moved ahead of another load of the same location (such a load may often optimized away by equivalencing the two pseudo registers).
Example (Revisited)

block1:
    ld  [a],Pr1
    ld  [b],Pr2
    add Pr1,Pr2,Pr3 ← Stall
    st  Pr3,[d]
    cmp Pr3,0
    be  block3

block2:
    mov 1,Pr4
    st  Pr4,[flag]
    b   block4

block3:
    st  0,[flag]

block4:
    ld  [d],Pr5
    ld  [g],Pr6
    sub Pr5,Pr6,Pr7 ← Stall
    st  Pr7,[f]

In B1 and B4, the number of available registers is irrelevant in avoiding stalls. There are too few independent instructions in each block.
Global Scheduling Restrictions (in Bernstein/Rodeh Heuristic)

1. Subprograms are divided into Regions. A region is a loop body or the subprogram body without enclosed loops.

2. Regions are scheduled inside-out.

3. Instructions never cross region boundaries.

4. All instructions move “upward” (to earlier positions in the instruction order).

5. The original order of branches is preserved.
Lesser (temporary) restrictions Include:
6. No code duplication.
7. Only 1-branch speculation.
8. No new basic blocks are created or added.
Scheduling Basic Blocks in a CFG

Basic blocks are visited and scheduled in Topological Order. Thus all of a block’s predecessors are scheduled before it is.

Two levels of scheduling are possible (depending on whether speculative execution is allowed or not):

1. When Basic Block A is scheduled, only Instructions in A and blocks equivalent to A that A dominates are considered. (Only “useful” instructions are considered.)
2. Blocks that are immediate successors of those considered in (1) are also considered. (This allows 1-branch speculation.)
Candidate Instructions

We first compute the set of basic blocks that may contribute instructions when block A is scheduled. (Either blocks equivalent to A or blocks at most 1-branch speculative.)
An individual Instruction, Inst, in this set of basic blocks may be scheduled in A if:

1. It is located in A.

2. It is in a block equivalent to A and may be moved across block boundaries. 
   (Some instructions, like calls, can’t be moved.)

3. It is not in a block equivalent to A, but may be scheduled speculatively. 
   (Some instructions, like stores, can’t be executed speculatively.)
Selecting Instructions to Issue

- A list of “ready to issue” instructions in block A and in blocks equivalent to A (or 1-branch distant from A) is maintained.
- All data dependencies must be satisfied and stalls avoided (if possible).
- N independent instructions are selected, where N is the processor’s issue-width.
- But what if more than N instructions are ready to issue?
- Selection is by Priority, using two Scheduling Heuristics.
Delay Heuristic

This value is computed on a per-basic block basis.

It estimates the worst-case delay (stalls) from an Instruction to the end of the basic block.

\[ D(I) = 0 \quad \text{if I is a leaf}. \]

Let \( d(I,J) \) be the delay if instruction \( J \) follows instruction \( I \) in the code schedule.

\[
D(I) = \max (D(J_i) + d(I,J_i)) \\
J_i \in \text{Succ}(I)
\]
Example of Delay Values

block1:
1. ld [a],Pr1
2. ld [b],Pr2
3. add Pr1,Pr2,Pr3
4. st Pr3,[d]
5. cmp Pr3,0
6. be block3

(Assume only loads can stall.)
Critical Path Heuristic

This value is also computed on a per-basic block basis.
It estimates how long it will take to execute Instruction I, and all I’s successors, assuming unlimited parallelism.

\[ \text{E}(I) = \text{Execution time for instruction I} \]
\[ \text{E}(I) \text{ (normally 1 for pipelined machines)} \]
\[ \text{CP}(I) = \text{E}(I) \text{ if } I \text{ is a leaf.} \]

\[ \text{CP}(I) = \text{E}(I) + \max \left( \text{CP}(J_i) + d(I,J_i) \right) \]
\[ J_i \in \text{Succ}(I) \]
Example of Critical Path Values

block1:
1. ld [a],Pr1
2. ld [b],Pr2
3. add Pr1,Pr2,Pr3
4. st Pr3,[d]
5. cmp Pr3,0
6. be block3
Selecting Instructions to Issue

From the Ready Set (instructions with all dependencies satisfied, and which will not stall) use the following priority rules:

1. Instructions in block A and blocks equivalent to A have priority over other (speculative) blocks.
2. Instructions with the highest D values have priority.
3. Instructions with the highest CP values have priority.

These rules imply that we schedule useful instructions before speculative ones, instructions on paths with potentially many stalls over those with fewer stalls, and instructions on critical paths over those on non-critical paths.
Example

block1:
1. ld [a],Pr1
2. ld [b],Pr2
3. add Pr1,Pr2,Pr3
4. st Pr3,[d]
5. cmp Pr3,0
6. be block3

block2:
7. mov 1,Pr4
8. st Pr4,[flag]
9. b block4

block3:
10. st 0,[flag]

block4:
11. ld [d],Pr5
12. ld [g],Pr6
13. sub Pr5,Pr6,Pr7
14. st Pr7,[f]
We’ll schedule without speculation; highest D values first, then highest CP values.

block1:
1. ld [a], Pr1
2. ld [b], Pr2
12. ld [g], Pr6
Next, come Instructions 3 and 4.

block1:
1. ld [a],Pr1
2. ld [b],Pr2
12. ld [g],Pr6
3. add Pr1,Pr2,Pr3
4. st Pr3,[d]
Now 11 can issue (D=1), followed by 5, 13, 6 and 14. Block B4 is now empty, so B3 and B4 are scheduled.

There are no stalls. In fact, if we equivalence Pr3 and Pr5, Instruction 11 can be removed.
Software Pipelining

Often loop bodies are too small to allow effective code scheduling. But loop bodies, being “hot spots,” are exactly where scheduling is most important.

Consider

void f (int a[], int last) {
    for (p=&a[0]; p!=&a[last]; p++)
        (*p)++;
}

The body of the loop might be:

L:  ld   [%g3],%g2
    nop
    add  %g2,1,%g2
    st   %g2,[%g3]
    add  %g3,4,%g3
    cmp  %g3,%g4
    bne  L
    nop
Scheduling this loop body is ineffective—each instruction depends upon its immediate predecessor.

So we have a loop body that takes 8 cycles to execute 6 “core” instructions.

We could unroll the loop body, but for how many iterations? What if the loop ends in the “middle” of an expanded loop body? Will extra registers be a problem?
In this case software pipelining offers a nice solution. We expand the loop body symbolically, intermixing instructions from several iterations. Instructions can overlap, increasing parallelism and forming a “tighter” loop body:

```
ld    [%g3],%g2
nop
add  %g2,1,%g2
L:    st   %g2,[%g3]
add  %g3,4,%g3
ld    [%g3],%g2
cmp  %g3,%g4
bne  L
add  %g2,1,%g2
```

Now the loop body is ideal—exactly 6 instructions. Also, no extra registers are needed!

But, we do “overshoot” the end of the loop a bit, loading one element past the exit point. (How serious is this?)
Reading Assignment

- Read Section 15.5, “Automatic Instruction Selection,” from Chapter 15.
- Read Pelegri- Llopard and Graham’s paper, “Optimal Code Generation from Expression Trees.” (Linked from the class Web page.)
- Read Fraser, Henry and Proebsting’s paper, “BURG- - Fast Optimal Instruction Selection and Tree Parsing.” (Linked from the class Web page.)
Key Insight of Software Pipelining

Software pipelining exploits the fact that a loop of the form \( \{A B C\}^n \), where A, B and C are individual instructions, and n is the iteration count, is equivalent to \( A \{B C A\}^{n-1} BC \) and is also equivalent to \( A B \{C A B\}^{n-1} C \).

Mixing instructions from several iterations may increase the effectiveness of code scheduling, and may perhaps allow for more parallel execution.

Software Pipelining is Hard

In fact, it is NP-complete:

Hsu and Davidson, “Highly concurrent scalar processing,” 13th ISCA (1986).
The Iteration Interval

We seek to initiate the next iteration of a loop as soon as possible, squeezing each iteration of the loop body into as few machine cycles as possible.

The general form of a software pipelined loop is:

- Prologue Code
- Kernel Code
- Epilogue Code
The prologue code “sets up” the main loop, and the epilogue code “cleans up” after loop termination. Neither the prolog nor the epilogue need be optimized, since they execute only once.

Optimizing the kernel is key in software pipelining. The kernel’s execution time (in cycles) is called the initiation interval (II); it measures how quickly the next iteration of a loop can start.

We want the smallest possible initiation interval. Determining the smallest viable II is itself NP-complete. Because of parallel issue and execution in superscalar and multiple issue processors, very small II values are possible (even less than 1!)
Factors that Limit the Size of the Initiation Interval

We want the initiation interval to be as small as possible. Two factors limit how small the II can become:

- Resource Constraints
- Dependency Constraints
Resource Constraints

A small II normally means that we are doing steps of several iterations simultaneously. The number of registers and functional units (that execute instructions) can become limiting factors of the size of II.

For example, if a loop body contains 4 floating point operations, and our processor can issue and execute no more than 2 floating point operations per cycle, then the loop’s II can’t be less than 2.
Dependency Constraints

A loop body can often contain a loop-carried dependence. This means one iteration of a loop depends on values computed in an earlier iteration. For example, in

```c
void f (int a[]) {
    for (i=1;i<1000;i++)
        a[i]=(a[i-1]+a[i])/2;
}
```

there is a loop carried dependence from the use of $a[i-1]$ to the computation of $a[i]$ in the previous iteration. This means the computation of $a[i]$ can’t begin until the computation of $a[i-1]$ is completed.

Let’s look at the code that might be generated for this loop:
The 6 marked instructions form a cyclic dependency chain from a use of \( a[i-1] \) to its computation (as \( a[i] \)) in the previous cycle. This cycle means that the loop’s II can never be less than 6.
Modulo Scheduling

There are many approaches to software pipelining. One of the simplest, and best known, is modulo scheduling. Modulo scheduling builds upon the postpass basic block schedulers we’ve already studied.

First, we estimate the II of the loop we will create. How?

We can compute the minimum II based on resource considerations ($II_{res}$) and the minimum II based on cyclic loop-carried dependencies ($II_{dep}$). Then $\max(II_{res}, II_{dep})$ is a reasonable estimate of the best possible II. We’ll try to build a loop with a kernel size of II. If this fails, we’ll try $II+1$, $II+2$, etc.
In modulo scheduling we’ll schedule instructions one by one, using the dependency dag and whatever heuristic we prefer to choose among multiple roots.

Now though, if we place an instruction at cycle \( c \) (many independent instructions may execute in the same cycle), then we’ll place additional copies of the instruction at cycle \( c+\Pi, c+2*\Pi, \) etc.

Placement must respect dependency constraints and resource limits at all positions. We consider placements only until a kernel (of size \( \Pi \)) forms. The kernel must begin before cycle \( s-1 \), where \( s \) is the size of the loop body (in instructions). The loop’s conditional branch is placed after the kernel is formed.
If we can’t form a kernel of size II (because of dependency or resource conflicts), we increase II by 1 and try again. At worst, we get a kernel equal in size to the original loop body, which guarantees that the modulo scheduler eventually terminates.

Depending on how many iterations are intermixed in the kernel, the loop termination condition may need to be adjusted (since the initial and final iterations may appear as part of the loop prologue and epilogue).
Example

Consider the following simple function which adds an array index to each element of an array and copies the results into a second array:

```c
void f (int a[], int b[]) {
    t1 = &a[0];
    t2 = &b[0];
    for (i=0; i<1000; i++, t1++, t2++)
        *t1 = *t2 + i;
}
```

The code for $f$ (compiled as a leaf procedure) is:
1. f: mov 0, %g3
2. L: ld [%o1], %g2
3. add %g3, %g2, %g4
4. st %g4, [%o0]
5. add %g3, 1, %g3
6. add %o0, 4, %o0
7. cmp %g3, 999
8. ble L
9. add %o1, 4, %o1
10. retl
11. nop

Dashed arcs are anti dependencies.
We’ll software pipeline the loop body, excluding the conditional branch (which is placed after the loop kernel is formed).

This loop body contains 2 loads/stores, 5 arithmetic and logical operations (including the compare) and one conditional branch.

Let’s assume the processor we are compiling for has 1 load/store unit, 3 arithmetic/logic units, and 1 branch unit. That means the processor can (ideally) issue and execute simultaneously 1 load or store, 3 arithmetic and logic instructions, and 1 branch. Thus its maximum issue width is 5. (Current superscalars have roughly this capability.)
Considering resource requirements, we will need at least two cycles to process the contents of the loop body. There are no loop-carried dependencies. 

Thus we will estimate this loop’s best possible Initiation Interval to be 2.

Since the only instruction that can stall is the root of the dependency dag, we’ll schedule using estimated critical path length, which is just the node’s height in the tree. Hence we’ll schedule the nodes in the order: 2,3,4,5,6,7,9.

We’ll schedule all instructions in a legal execution order (respecting dependencies), and we’ll try to choose as many instructions as possible to execute in the same cycle.
Starting with the root, instruction 2, we schedule it at cycles 1, 3 (=1+II), 5 (=1+2*II):

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>2.</td>
<td></td>
</tr>
<tr>
<td>3.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>4.</td>
<td></td>
</tr>
<tr>
<td>5.</td>
<td>ld [%o1], %g2</td>
</tr>
</tbody>
</table>

No conflicts so far, since each of the loads starts an independent iteration.
We’ll schedule instruction 3 next. It must be placed at cycles 3, 5 and 7 since it uses the result of the load.

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>2.</td>
<td></td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>3.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>4.</td>
<td></td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>5.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>6.</td>
<td></td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, %g2, %g4</td>
</tr>
</tbody>
</table>

Note that in cycles 3 and 5 we use the current value of %g2 and initiate a load into %g2.
Instruction 4 is next. It uses the result of the add we just scheduled, so it is placed at cycles 4 and 6.

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>2.</td>
<td></td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>3.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>4.</td>
<td>st %g4, [%o0]</td>

<td>add %o0, 4, %o0</td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, 1, %g3</td>
</tr>
</tbody>
</table>
Next we place instruction 7. It uses the result of instruction 5 (%g3), so it is placed in the cycles following instruction 5 (4 and 6).

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [o1], g2</td>
</tr>
<tr>
<td>2.</td>
<td></td>
</tr>
<tr>
<td>3.</td>
<td>add g3, g2, g4</td>
</tr>
<tr>
<td>3.</td>
<td>ld [o1], g2</td>
</tr>
<tr>
<td>3.</td>
<td>add g3, 1, g3</td>
</tr>
<tr>
<td>4.</td>
<td>st g4, [o0]</td>
</tr>
<tr>
<td>4.</td>
<td>add o0, 4, o0</td>
</tr>
<tr>
<td>4.</td>
<td>cmp g3, 999</td>
</tr>
<tr>
<td>5.</td>
<td>add g3, g2, g4</td>
</tr>
<tr>
<td>5.</td>
<td>ld [o1], g2</td>
</tr>
<tr>
<td>5.</td>
<td>add g3, 1, g3</td>
</tr>
<tr>
<td>6.</td>
<td>st g4, [o0]</td>
</tr>
<tr>
<td>6.</td>
<td>add o0, 4, o0</td>
</tr>
<tr>
<td>7.</td>
<td>add g3, g2, g4</td>
</tr>
<tr>
<td>7.</td>
<td>add g3, 1, g3</td>
</tr>
<tr>
<td>7.</td>
<td>cmp g3, 999</td>
</tr>
</tbody>
</table>
Finally we place instruction 9. It is anti dependent on instruction 2 so it is placed in the same cycles as instruction 3 (1, 3 and 5).

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>1.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>3.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>3.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>4.</td>
<td>st %g4, [%o0]</td>
</tr>
<tr>
<td>4.</td>
<td>add %o0, 4, %o0</td>
</tr>
<tr>
<td>4.</td>
<td>cmp %g3, 999</td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>5.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>5.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>6.</td>
<td>st %g4, [%o0]</td>
</tr>
<tr>
<td>6.</td>
<td>add %o0, 4, %o0</td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>7.</td>
<td>cmp %g3, 999</td>
</tr>
</tbody>
</table>
We look for a 2 cycles kernel that contains all 7 instructions of the loop body that we have scheduled. We also want a kernel that sets the condition code (via the cmp) during its first cycle so that it can be tested during its second (and final) cycle. Cycles 4 and 5 meet these criteria, and will form our kernel.

We place the conditional branch just before the last instruction in cycle 5 (to give the conditional branch a useful instruction for its delay slot).
We now have:

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>1.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>3.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>3.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>4.</td>
<td>L: st %g4, [%o0]</td>
</tr>
<tr>
<td>4.</td>
<td>add %o0, 4, %o0</td>
</tr>
<tr>
<td>4.</td>
<td>cmp %g3, 999</td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>5.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>5.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>5.</td>
<td>ble L</td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>6.</td>
<td>st %g4, [%o0]</td>
</tr>
<tr>
<td>6.</td>
<td>add %o0, 4, %o0</td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>7.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>7.</td>
<td>cmp %g3, 999</td>
</tr>
</tbody>
</table>
A couple of final issues must be dealt with:

- Does the iteration count need to be changed?
  In this case no, since the final valid value of \( i \), 999, is used to compute \( g_4 \) in cycle 5, before the loop exits.

- What instructions do we keep as the loop’s epilogue?
  None! Instructions past the kernel aren’t needed since they are part of future iterations (past \( i==999 \)) which aren’t needed or wanted.

- Note that \( b[1000] \) and \( b[1001] \) are “touched” even though they are never used. This is probably OK as long as arrays aren’t placed at the very end of a page or segment.
Our final loop is:

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>1.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>3.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>3.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, 1, %g3</td>
</tr>
<tr>
<td>4.</td>
<td>L: st %g4, [%o0]</td>
</tr>
<tr>
<td>4.</td>
<td>add %o0, 4, %o0</td>
</tr>
<tr>
<td>4.</td>
<td>cmp %g3, 999</td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, %g2, %g4</td>
</tr>
<tr>
<td>5.</td>
<td>ld [%o1], %g2</td>
</tr>
<tr>
<td>5.</td>
<td>add %o1, 4, %o1</td>
</tr>
<tr>
<td>5.</td>
<td>ble L</td>
</tr>
<tr>
<td>5.</td>
<td>add %g3, 1, %g3</td>
</tr>
</tbody>
</table>

This is very efficient code—we use the full parallelism of the processor, executing 5 instructions in cycle 5 and 8 instructions in just 2 cycles. All resource limitations are respected.
False Dependencies & Loop Unrolling

A limiting factor in how “tightly” we can software pipeline a loop is reuse of registers and the false dependencies reuse induces.

Consider the following simple function that copies array elements:

```c
void f (int a[], int b[], int lim) {
    for (i=0; i<lim; i++)
        a[i] = b[i];
}
```

The loop that is generated takes 3 cycles:

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>L: ld [%g3+%o1], %g2</td>
</tr>
<tr>
<td>1.</td>
<td>addcc %o2, -1, %o2</td>
</tr>
<tr>
<td>3.</td>
<td>st %g2, [%g3+%o0]</td>
</tr>
<tr>
<td>3.</td>
<td>bne L</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, 4, %g3</td>
</tr>
</tbody>
</table>
We’d like to tighten the iteration interval to 2 or less. One cycle is unlikely, since doing a load and a store in the same cycle is problematic (due to a possible dependence through memory).

If we try to use modulo scheduling, we can’t put a second copy of the load in cycle 2 because it would overwrite the contents of the first load. A load in cycle 3 will clash with the store.

The solution is to unroll the loop into two copies, using different registers to hold the contents of the load and the current offset into the arrays.

The use of a “count down” register to test for loop termination is helpful,
since it allows an easy exit from the middle of the loop.

With the renaming of the registers used in the two expanded iterations, scheduling to “tighten” the loop is effective.

After expansion we have:

<table>
<thead>
<tr>
<th>cycle</th>
<th>instruction</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. L:</td>
<td>ld [%g3+o1], %g2</td>
</tr>
<tr>
<td>1.</td>
<td>addcc %o2, -1, %o2</td>
</tr>
<tr>
<td>3.</td>
<td>st %g2, [%g3+o0]</td>
</tr>
<tr>
<td>3.</td>
<td>beq L2</td>
</tr>
<tr>
<td>3.</td>
<td>add %g3, 4, %g4</td>
</tr>
<tr>
<td>4.</td>
<td>ld [%g4+o1], %g5</td>
</tr>
<tr>
<td>4.</td>
<td>addcc %o2, -1, %o2</td>
</tr>
<tr>
<td>6.</td>
<td>st %g5, [%g4+o0]</td>
</tr>
<tr>
<td>6.</td>
<td>bne L</td>
</tr>
<tr>
<td>6.</td>
<td>add %g4, 4, %g3</td>
</tr>
</tbody>
</table>

L2:

We still have 3 cycles per iteration, because we haven’t scheduled yet.
Now we can move the increment of %g3 (into %g4) above other uses of %g3. Moreover, we can move the load into %g5 above the store from %g2 (if the load and store are independent):

cycle instruction
1. L:     ld    [%g3+%o1], %g2
1.          addcc %o2, -1, %o2
1.          add %g3, 4, %g4
2.          ld    [%g4+%o1], %g5
3.          st    %g2, [%g3+%o0]
3.          beq   L2
3.          addcc %o2, -1, %o2
4.          st    %g5, [%g4+%o0]
4.          bne   L
4.          add %g4, 4, %g3

L2:

We can normally test whether %g4+%o1 and %g3+%o0 can be equal at compile-time, by looking at the actual array parameters. (Can &a[0] == &b[1]?)
Automatic Instruction Selection

Besides register allocation and code scheduling, a code generator must also do Instruction Selection.

For CISC (Complex Instruction Set Computer) Architectures, like the Intel x86, DEC Vax, and many special purpose processors (like Digital Signal Processors), instruction selection is often challenging because so many choices exist.

In the Vax, for example, one, two and three address instructions exist. Each address may be a register, memory location (with or without indexing), or an immediate operand.
For RISC (Reduced Instruction Set Computer) Processors, instruction formats and addressing modes are far more limited.

Still, it is necessary to handle immediate operands, commutative operands and special case null operands (add of 0 or multiply of 1).

Moreover, automatic instruction selection supports automatic retargeting of a compiler to a new or extended instruction set.
Tree-Structured Intermediate Representations

For purposes of automatic code generation, it is convenient to translate a source program into a Low-level, Tree-Structured IR. This representation exposes translation details (how locals are accessed, how conditionals are translated, etc.) without assuming a particular instruction set.

In a low-level, tree-structured IR, leaves are registers or bit-patterns and internal nodes are machine-level primitives, like load, store, add, etc.
Example

Let's look at how

\[ a = b - 1; \]

is represented, where \( a \) is a global integer variable and \( b \) is a local (frame allocated) integer variable.

![Diagram showing the representation of the expression]

- \( a_{\text{adr}} \)
- \( \ast \) IntLiteral\(_1\)
- +
- %fp
- \( b_{\text{offset}} \)
Representation of Instructions

Individual instructions can be represented as trees, rooted by the operation they implement.

For example:

Renovable as trees, rooted by the operation they implement.

For example:

\[
\text{Reg} \rightarrow \begin{array}{c}
\ast \\
\text{Adr}
\end{array}
\]

This is an instruction that loads a register with the value at an absolute address.

\[
\text{Reg} \rightarrow \begin{array}{c}
+ \\
\text{Reg} \\
\text{Reg}
\end{array}
\]

This is an instruction that adds the contents of two registers and stores the sum into a third register.
Using the above pair of instruction definitions, we can repeatedly match instructions in the following program IR:
Each match of an instruction pattern can have the side-effect of generating an instruction:

```plaintext
ld [a],%R1
ld [b],%R2
add %R1,%R2,%R3
ld [c],%R4
add %R3,%R4,%R5
```

Registers can be allocated on-the-fly as Instructions are generated or instructions can be generated using pseudo-registers, with a subsequent register allocation phase.

Using this view of instruction selection, choosing instructions involves finding a cover for an IR tree using Instruction Patterns. Any cover is a valid translation.
Tree Parsing vs. String Parsing

This process of selecting instructions by matching instruction patterns is very similar to how strings are parsed using Context-free Grammars.

We repeatedly identify a sub-tree that corresponds to an instruction, and simplify the IR-tree by replacing the instruction sub-tree with a nonterminal symbol. The process is repeated until the IR-tree is reduced to a single nonterminal.

The theory of reducing an IR-tree using rewrite rules has been studied as part of BURS (Bottom-Up Rewrite Systems) Theory by Pelegri-Llopart and Graham.
Automatic Instruction
Selection Tools

Just as tools like Yacc and Bison automatically generate a string parser from a specification of a Context-free Grammar, there exist tools that will automatically generate a tree-parser from a specification of tree productions.

Two such tools are BURG (Bottom Up Rewrite Generator) and IBURG (Interpreted BURG). Both automatically generate parsers for tree grammars using BURS theory.
Least-Cost Tree Parsing

BURG (and IBURG) guarantee to find a cover for an input tree (if one exists).

But tree grammars are usually very ambiguous.

Why?—Because there is usually more than one code sequence that can correctly implement a given IR-tree.

To deal with ambiguity, BURG and IBURG allow each instruction pattern (tree production) to have a cost.

This cost is typically the size or execution time for the corresponding target-machine instructions.
Using costs, BURG (and IBURG) not only guarantee to find a cover, but also a least-cost cover.

This means that when a generated tree-parser is used to cover (and thereby translate) an IR-Tree, the best possible code sequence is guaranteed.

If more than one least-cost cover exists, an arbitrary choice is made.
Using BURG to Specify Instruction Selection

We’ll need a tree grammar to specify possible partial covers of a tree. For simplicity, BURG requires that all tree productions be of the form

\[ A \rightarrow b \]

(where \( b \) is a single terminal symbol)

or

\[ A \rightarrow \text{Op}(B,C, ...) \]

(where \( \text{Op} \) is a terminal that is a subtree root and \( B,C, ... \) are non-terminals)

\[ A \rightarrow \text{Op}(B,C, ...) \]

denotes

\[ \begin{array}{c}
\text{Op} \\
\downarrow \\
B \quad C \quad ...
\end{array} \]
All tree grammars can be put into this form by adding new nonterminals and productions as needed.

We must specify terminal symbols (leaves and operators in the IR-Tree) and nonterminals that are used in tree productions.
**Example**

A subset of a SPARC instruction selector.

**Terminals**

**Leaf Nodes**

- `int32` (32 bit integer)
- `s13` (13 bit signed integer)
- `r` (0-31, a register name)

**Operator Nodes**

- `*` (unary indirection)
- `-` (binary minus)
- `+` (binary addition)
- `=` (binary assignment)
Nonterminals

UInt (32 bit unsigned integer)
Reg (Loaded register value)
Imm (Immediate operand)
Adr (Address expression)
Void (Null value)
# Productions

<table>

</tbody>
</table>
Reading Assignment

- Read pages 1-30 of “Automatic Program Optimization,” by Ron Cytron. (Linked from the class Web page.)
Example

Let's look at instruction selection for

\[ a = b - 1; \]

where \( a \) is a global int, accessed with a 32 bit address and \( b \) is a local int, accessed as an offset from the frame pointer.

```
int32 -
  *
  +
  r
  s13
  s13
```
We match tree nodes *bottom-up*. Each node is labeled with the nonterminals it can be reduced to, the production used to produce the nonterminal, and the cost to generate the node (and its children) from the nonterminal.

We match leaves first:

\[
\begin{align*}
\text{Int:} & \text{R0:0} \\
\text{Reg:} & \text{R6:2} \\
\text{Int:} & 32
\end{align*}
\]
We now work upward, considering operators whose children have been labeled. Again, if an operator can be generated by a nonterminal, we mark the operator with the nonterminal, the production used to generate the operator, and the total cost (including the cost to generate all children).

If a nonterminal can generate the operator using more than one production, the least-cost derivation is chosen.

When we reach the root, the nonterminal with the lowest overall cost is used to generate the tree.
\[
\text{Void:R10:4} = \text{int32} - \text{Reg:R8:2} \\
\text{Reg:R6:2} \times \text{Reg:R9:1} \text{S13} \text{Imm:R4:0 Reg:R5:1} \\
\text{Reg:R1:0} + \text{Adr:R3:0} r \text{S13} \text{Imm:R4:0 Reg:R5:1}
\]
Note that once we know the production used to generate the root of the tree, we know the productions used to generate each subtree too:

```
=  Void:R10:4
  
  UInt:R0:0
  int32

  Reg:R8:2
  s13 Imm:R4:0

  Reg:R9:1
  *

  Adr:R3:0
  +

  Reg:R1:0
  r

  s13 Imm:R4:0
```
We generate code by doing a depth-first traversal, generating code for a production after all the production’s children have been processed.

We need to do register allocation too; for our example, a simple on-the-fly generator will suffice.

```
➊ ld    [%fp+b],%l0
➋ sub   %l0,1,%l0
➌ sethi %hi(a),%g1
st    %l0,[%g1+%lo(a)]
```
Had we translated a slightly difference expression,

\[ a = b - 1000000; \]

we would automatically get a different code sequence (because 1000000 is an int32 rather than an s13):

\[
\begin{align*}
    &\text{ld} [\%fp+b],\%l0 \\
    &\text{sethi} \%hi(1000000),\%g1 \\
    &\text{or} \%g1,\%lo(1000000),\%l1 \\
    &\text{sub} \%l0,\%l1,\%l0 \\
    &\text{sethi} \%hi(a),\%g1 \\
    &\text{st} \%l0, [\%g1+%lo(a)]
\end{align*}
\]
Adding New Rules

Since instruction selectors can be automatically generated, it’s easy to add “extra” rules that handle optimizations or special cases. For example, we might add the following to handle addition of a left immediate operand or subtraction of 0 from a register:

<table>
<thead>
<tr>
<th>Rule #</th>
<th>Production</th>
<th>Cost</th>
<th>SPARC Code</th>
</tr>
</thead>
<tbody>
<tr>
<td>R11</td>
<td>Reg → (\text{Imm} + \text{Reg})</td>
<td>1</td>
<td>add Reg, Imm, Reg</td>
</tr>
<tr>
<td>R12</td>
<td>Reg → (\text{Reg} - \text{Zero})</td>
<td>0</td>
<td></td>
</tr>
</tbody>
</table>
Improving the Speed of Instruction Selection

As we have presented it, instruction selection looks rather slow—for each node in the IR tree, we must match productions, compare costs, and select least-cost productions.

Since compilers routinely generate programs with tens or hundreds of thousands of instructions, doing a lot of computation to select one instruction (even if it’s the best instruction) could be too slow.

Fortunately, this need not be the case. Instruction selection using BURS can be made very fast.
Adding States to BURG

We can precompute a set of states that represent possible labelings on IR tree nodes. A table of node names and subtree states then is used to select a node’s state. Thus labeling becomes nothing more than repeated table lookup.

For example, we might create a state s0 that corresponds to the labeling \{Reg:R1:0, Adr:R2:0\}.

A state selection function, label, defines label(r) = s0. That is, whenever r is matched as a leaf, it is to be labeled with s0.

If a node is an operator, label uses the name of the operator and the labeling
assigned to its children to choose the operator’s label. For example,
label(+, s0, s1) = s2
says that a + with children labeled as s0 and s1 is to be labeled as s2.

In theory, that’s all there is to building a fast instruction selector.

We generate possible labelings, encode them as states, and table all combinations of labelings.

But,

how do we know the set of possible labelings is even finite?

In fact, it isn’t!
Normalizing Costs

It is possible to generate states that are identical except for their costs. For example, we might have
\[ s_1 = \{ \text{Reg:R1:0}, \text{Adr:R2:0} \}, \]
\[ s_2 = \{ \text{Reg:R1:1}, \text{Adr:R2:1} \}, \]
\[ s_3 = \{ \text{Reg:R1:2}, \text{Adr:R2:2} \}, \]
etc.

Here an important insight is needed—the absolute costs included in states aren’t really essential. Rather relative costs are what is important. In \( s_1, s_2, \) and \( s_3, \) Reg and Adr have the same cost. Hence the same decision in choosing between Reg and Adr will be made in all three states.
We can limit the number of states needed by normalizing costs within states so that the lowest cost choice is always 0, and other costs are differences (deltas) from the lowest cost choice.

This observation keeps costs bounded within states (except for pathologic cases).

Using additional techniques to further reduce the number of states needed, and the time needed to generate them, fast and compact BURS instruction selectors are achievable. See

“Simple and Efficient BURS Table Generation,” T. Proebsting, 1992 PLDI Conference.
Example

</tbody>
</table>
We start by looking up the state assigned to each leaf. We then work upward, choosing the state of a parent based on the parent’s kind and the states assigned to the children. These are all table lookups, and hence very fast.

At the root, we select the nonterminal and production based on the state assigned to the root (any entry with 0 cost). Knowing the production used at the root tells us the nonterminal used at each child. Each state has only one entry per nonterminal, so knowing a node’s state and the nonterminal used to generate it immediately tells us the production used. Hence identifying the production used for each node is again very fast.
Step 1 (Label leaves with states):

\[
\begin{align*}
\text{int32} & \quad = \\
\left( s_0 \times r \right) & \quad + \quad s_{13} \\
\left( s_4 \right) & \quad = \\
\end{align*}
\]

Step 2 (Propagate states upward):

\[
\begin{align*}
\text{int32} & \quad = \\
\left( s_0 \times r \right) & \quad + \quad s_{13} \\
\left( s_4 \right) & \quad = \\
\end{align*}
\]
Step 3 (Choose production used at root): R10.

Step 4 (Propagate productions used downward to children):

```
  = R10
 /    \
|     |
R0    int32
 /     /
R9    -   R8
   /     /
  R3    s13 R4
     /   /
    R1  s13 R4
```
Data Flow Frameworks

- Data Flow Graph:
  Nodes of the graph are basic blocks or individual instructions.
  Arcs represent flow of control.

Forward Analysis:
  Information flow is the same direction as control flow.

Backward Analysis:
  Information flow is the opposite direction as control flow.

Bi-directional Analysis:
  Information flow is in both directions. (Not too common.)
• **Meet Lattice**

  Represents solution space for the data flow analysis.

![Diagram of Meet Lattice]

• **Meet operation**
  (And, Or, Union, Intersection, etc.)

  Combines solutions from predecessors or successors in the control flow graph.
Transfer Function

Maps a solution at the top of a node to a solution at the end of the node (forward flow)
or
Maps a solution at the end of a node to a solution at the top of the node (backward flow).
Example: Available Expressions

This data flow analysis determines whether an expression that has been previously computed may be reused.

Available expression analysis is a forward flow problem—computed expression values flow forward to points of possible reuse.

The best solution is True—the expression may be reused.

The worst solution is False—the expression may not be reused.
The Meet Lattice is:

T (Expression is Available)

F (Expression is Not Available)

As initial values, at the top of the start node, nothing is available. Hence, for a given expression, 

\[ \text{AvailIn}(b_0) = \text{F} \]

We choose an expression, and consider all the variables that contribute to its evaluation. 

Thus for \( e_1 = a + b - c \), a, b and c are \( e_1 \)'s operands.
The transfer function for $e_1$ in block $b$ is defined as:

If $e_1$ is computed in $b$ after any assignments to $e_1$’s operands in $b$
Then $\text{AvailOut}(b) = T$
Elsif any of $e_1$’s operands are changed after the last computation of $e_1$ or $e_1$’s operands are changed without any computation of $e_1$
Then $\text{AvailOut}(b) = F$
Else $\text{AvailOut}(b) = \text{AvailIn}(b)$

The meet operation (to combine solutions) is:

$$\text{AvailIn}(b) = \bigwedge_{p \in \text{Pred}(b)} \text{AvailOut}(p)$$
Example: $e_1 = v + w$

```
v = 9
```
```
y = v + w
```

```
w = 5
```

```
x = v + w
```

```
z = v + w
```

```
stop
```

```
v = 2
```

```

```
F
```
Circularities Require Care

Since data flow values can depend on themselves (because of loops), care is required in assigning initial “guesses” to unknown values. Consider

\[ z = v + w \]

If the flow value on the loop backedge is initially set to false, it can never become true. (Why?) Instead we should use True, the identity for the AND operation.
Reading Assignment

- Read pages 31-62 of “Automatic Program Optimization,” by Ron Cytron. (Linked from the class Web page.)
**Very Busy Expressions**

This is an interesting variant of available expression analysis.

An expression is *very busy at a point* if it is *guaranteed* that the expression will be computed at some time in the future.

Thus starting at the point in question, the expression must be reached before its value changes.

Very busy expression analysis is a backward flow analysis, since it propagates information about future evaluations backward to “earlier” points in the computation.
The meet lattice is:

\[ T \text{ (Expression is Very Busy)} \]
\[ F \text{ (Expression is Not Very Busy)} \]

As initial values, at the end of all exit nodes, nothing is very busy. Hence, for a given expression, 
\[ \text{VeryBusyOut}(b_{last}) = F \]
The transfer function for $e_1$ in block $b$ is defined as:

If $e_1$ is computed in $b$ before any of its operands
Then $\text{VeryBusyIn}(b) = T$
Elsif any of $e_1$'s operands are changed before $e_1$ is computed
Then $\text{VeryBusyIn}(b) = F$
Else $\text{VeryBusyIn}(b) = \text{VeryBusyOut}(b)$

The meet operation (to combine solutions) is:

$$\text{VeryBusyOut}(b) = \mathbf{AND} \; \text{VeryBusyIn}(s) \; \text{for all } s \in \text{Succ}(b)$$
Example: $e_1 = v + w$

\[
\begin{align*}
v &= 2 \\
w &= 5 \\
x &= v + w \\
u &= v + w \\
\text{stop}
\end{align*}
\]
v = 2
F
v = 3
F
w = 5
F
x = v + w

F
stop
F
Identifying Identical Expressions

We can hash expressions, based on hash values assigned to operands and operators. This makes recognizing potentially redundant expressions straightforward.

For example, if $H(a) = 10$, $H(b) = 21$ and $H(+) = 5$, then (using a simple product hash),

$$H(a+b) = 10 \times 21 \times 5 \mod \text{TableSize}$$
Effects of Aliasing and Calls

When looking for assignments to operands, we must consider the effects of pointers, formal parameters and calls.

An assignment through a pointer (e.g., \( *p = val \)) kills all expressions dependent on variables \( p \) might point to. Similarly, an assignment to a formal parameter kills all expressions dependent on variables the formal might be bound to.

A call kills all expressions dependent on a variable changeable during the call.

Lacking careful alias analysis, pointers, formal parameters and calls can kill all (or most) expressions.
Very Busy Expressions and Loop Invariants

Very busy expressions are ideal candidates for invariant loop motion. If an expression, invariant in a loop, is also very busy, we know it must be used in the future, and hence evaluation outside the loop must be worthwhile.
for (...) {
    if (...){
        a=b+c;
        else a=d+c;
    }
}

for (...) {
    if (a>b+c)
        x=1;
    else x=0;
}

\[ \text{\texttt{t=b+c}} \]
\[ \text{T} \quad \text{F} \]
\[ \text{T} \quad \text{F} \]
\[ \text{\texttt{a=b+c}} \quad \text{\texttt{a=d+c}} \]
\[ \text{\texttt{b+c}} \text{ is not very busy at loop entrance} \]

\[ \text{\texttt{t=b+c}} \]
\[ \text{T} \quad \text{F} \]
\[ \text{\texttt{a=b+c}} \]
\[ \text{\texttt{b+c}} \text{ is very busy at loop entrance} \]
Reaching Definitions

We have seen reaching definition analysis formulated as a set-valued problem. It can also be formulated on a per-definition basis.

That is, we ask “What blocks does a particular definition to v reach?”

This is a boolean-valued, forward flow data flow problem.
Initially, $\text{DefIn}(b_0) = \text{false}$.

For basic block $b$:

$\text{DefOut}(b) =$

If the definition being analyzed is the last definition to $v$ in $b$
Then True
Elsif any other definition to $v$ occurs in $b$
Then False
Else $\text{DefIn}(b)$

The meet operation (to combine solutions) is:

$$\text{DefIn}(b) = \bigvee_{p \in \text{Pred}(b)} \text{DefOut}(p)$$

To get all reaching definition, we do a series of single definition analyses.
Live Variable Analysis

This is a boolean-valued, backward flow data flow problem.

Initially, LiveOut(b_{last}) = false.

For basic block b:

LiveIn(b) =

If the variable is used before it is defined in b
Then True
Elsif it is defined before it is used in b
Then False
Else LiveOut(b)

The meet operation (to combine solutions) is:

LiveOut(b) = \bigvee_{s \in \text{Succ}(b)} LiveIn(s)
Bit Vectoring Data Flow Problems

The four data flow problems we have just reviewed all fit within a single framework.

Their solution values are Booleans (bits).

The meet operation is And or OR.

The transfer function is of the general form

\[ \text{Out}(b) = (\text{In}(b) - \text{Kill}_b) \cup \text{Gen}_b \]

or

\[ \text{In}(b) = (\text{Out}(b) - \text{Kill}_b) \cup \text{Gen}_b \]

where \( \text{Kill}_b \) is true if a value is “killed” within \( b \) and \( \text{Gen}_b \) is true if a value is “generated” within \( b \).
In Boolean terms:
Out(b) = (In(b) AND Not Kill\textsubscript{b}) OR Gen\textsubscript{b}
or
In(b) = (Out(b) AND Not Kill\textsubscript{b}) OR Gen\textsubscript{b}

An advantage of a bit vectoring data flow problem is that we can do a series of data flow problems “in parallel” using a bit vector.

Hence using ordinary word-level ANDs, ORs, and NOTs, we can solve 32 (or 64) problems simultaneously.
Example

Do live variable analysis for u and v, using a 2 bit vector:

We expect no variable to be live at the start of $b_0$. (Why?)
Depth-First Spanning Trees

Sometimes we want to “cover” the nodes of a control flow graph with an acyclic structure.

This allows us to visit nodes once, without worrying about cycles or infinite loops.

Also, a careful visitation order can approximate forward control flow (very useful in solving forward data flow problems).

A Depth-First Spanning Tree (DFST) is a tree structure that covers the nodes of a control flow graph, with the start node serving as root of the DFST.
Building a DFST

We will visit CFG nodes in depth-first order, keeping arcs if the visited node hasn’t be reached before.

To create a DFST, T, from a CFG, G:

1. T ← empty tree
2. Mark all nodes in G as “unvisited.”
3. Call DF(start node)

DF (node) {
1. Mark node as visited.
2. For each successor, s, of node in G:
   If s is unvisited
   (a) Add node → s to T
   (b) Call DF(s)
Example

Visit order is A, B, C, D, E, G, H, I, J, F
The DFST is

A
  ↘
  B
  ↘
  C
  ↘
  D
  ↘
  E  F
  ↘  ↘
  G  H
  ↘  ↘
  I  J
Categorizing Arcs using a DFST

Arcs in a CFG can be categorized by examining the corresponding DFST.
An arc $A \rightarrow B$ in a CFG is

(a) An Advancing Edge if $B$ is a proper descendent of $A$ in the DFST.

(b) A Retreating Edge if $B$ is an ancestor of $A$ in the DFST. (This includes the $A \rightarrow A$ case.)

(c) A Cross Edge if $B$ is neither a descendent nor an ancestor of $A$ in the DFST.
Example

A
  ↓
  B
  ↓
  C
  ↓
  D
  ↓
  E
  ↓
  F
  ↓
  G
  ↓
  H
  ↓
  I
  ↓
  J

Arrows indicate transitions: a, r, c.
Depth-First Order

Once we have a DFST, we can label nodes with a Depth-First Ordering (DFO).

Let $i =$ the number of nodes in a CFG (= the number of nodes in its DFST).

DFO(node) {
    For (each successor $s$ of node) do
        DFO($s$);
    Mark node with $i$;
    $i--$;
}

Example

The number of nodes = 10.
Application of Depth-First Ordering

- Retreating edges (a necessary component of loops) are easy to identify:
  \[ a \rightarrow b \text{ is a retreating edge if and only if } dfo(b) \leq dfo(a) \]

- A depth-first ordering in an excellent visit order for solving forward data flow problems. We want to visit nodes in essentially topological order, so that all predecessors of a node are visited (and evaluated) before the node itself is.
Dominators

A CFG node $M$ dominates $N$ 
($M \text{ dom } N$) if and only if all paths from the start node to $N$ must pass through $M$.

A node trivially dominates itself.
Thus $(N \text{ dom } N)$ is always true.

A CFG node $M$ strictly dominates $N$ 
($M \text{ sdom } N$) if and only if 
($M \text{ dom } N$) and $M \neq N$.
A node can’t strictly dominates itself.
Thus $(N \text{ sdom } N)$ is never true.
A CFG node may have many dominators.

Node F is dominated by F, E, D and A.
Immediate Dominators

If a CFG node has more than one dominator (which is common), there is always a unique “closest” dominator called its immediate dominator.

(M idom N) if and only if
(M sdom N) and
(P sdom N) ⇒ (P dom M)

To see that an immediate dominator always exists (except for the start node) and is unique, assume that node N is strictly dominated by M₁, M₂, ..., Mₚ, P ≥ 2.

By definition, M₁, ..., Mₚ must appear on all paths to N, including acyclic paths.
Look at the relative ordering among $M_1$ to $M_p$ on some arbitrary acyclic path from the start node to $N$. Assume that $M_i$ is “last” on that path (and hence “nearest” to $N$).

If, on some other acyclic path, $M_j \neq M_i$ is last, then we can shorten this second path by going directly from $M_i$ to $N$ without touching any more of the $M_1$ to $M_p$ nodes. But, this totally removes $M_j$ from the path, contradicting the assumption that $(M_j \text{ sdom } N)$. 
Dominator Trees

Using immediate dominators, we can create a dominator tree in which $A \rightarrow B$ in the dominator tree if and only if $(A \text{ idom } B)$.
Note that the Dominator Tree of a CFG and its DFST are distinct trees (though they have the same nodes).
A Dominator Tree is a compact and convenient representation of both the dom and idom relations.

A node in a Dominator Tree dominates all its descendents in the tree, and immediately dominates all its children.
Computing Dominators

Dominator can be computed as a Set-valued Forward Data Flow Problem.

If a node $N$ dominates all of node $M$’s predecessors, then $N$ appears on all paths to $M$. Hence $(N \text { dom } M)$.

Similarly, if $M$ doesn’t dominate all of $M$’s predecessors, then there is a path to $M$ that doesn’t include $M$. Hence $\neg(N \text { dom } M)$.

These observations give us a “data flow equation” for dominator sets:

$$
dom(N) = \{N\} \cup \bigcap_{M \in \text{Pred}(N)} \text{dom}(M)
$$
The analysis domain is the lattice of all subsets of nodes. Top is the set of all nodes; bottom is the empty set. The ordering relation is subset.

The meet operation is intersection.

The Initial Condition is that

\[ \text{DomIn}(b_0) = \emptyset \]

\[ \text{DomIn}(b) = \bigcap \text{DomOut}(c) \quad c \in \text{Pred}(b) \]

\[ \text{DomOut}(b) = \text{DomIn}(b) \cup \{b\} \]
Loops Require Care

Loops in the Control Flow Graph induce circularities in the Data Flow equations for Dominators. In

we have the rule \( \text{dom}(B) = \text{DomOut}(B) = \text{DomIn}(B) \cup \{B\} = \{B\} \cup (\text{DomOut}(B) \cap \text{DomOut}(A)) \)

If we choose \( \text{DomOut}(B) = \emptyset \) initially, we get \( \text{DomOut}(B) = \{B\} \cup (\emptyset \cap \text{DomOut}(A)) = \{B\} \)

which is wrong.
Instead, we should use the Universal Set (of all nodes) which is the identity for $\cap$.

Then we get $\text{DomOut}(B) = \{B\} \cup \left(\{\text{all nodes}\} \cap \text{DomOut}(A)\right) = \{B\} \cup \text{DomOut}(A)$ which is correct.
A Worklist Algorithm for Dominators

The data flow equations we have developed for Dominators can be evaluated using a simple Worklist Algorithm.

Initially, each node’s dominator set is set to the set of all nodes. We add the start node to our worklist.

For each node on the worklist, we reevaluate its dominator set. If the set changes, the updated dominator set is used, and all the node’s successors are added to the worklist (so that the updated dominator set can be propagated).
The algorithm terminates when the worklist becomes empty, indicating that a stable solution has been found.

Compute Dominators()

For (each \( n \in \text{NodeSet} \))
\[
\text{Dom}(n) = \text{NodeSet}
\]

WorkList = \{StartNode\}

While (WorkList \( \neq \emptyset \)) {
  Remove any node \( Y \) from WorkList
  New = \{\( Y \}\} \cup \bigcap \text{Dom}(X)
  X \in \text{Pred}(Y)

  If New \( \neq \text{Dom}(Y) \) {
    \text{Dom}(Y) = \text{New}
    \text{For (each} \ Z \in \text{Succ}(Y))
    \text{WorkList = WorkList U} \ \{Z\}
  }
}

Example

Initially the WorkList = \{Start\}.
Be careful when Pred(Node) = \phi.
Control Flow Graph

Dominator Tree
Postdominance

A block Z postdominates a block Y (Z \text{ pdom } Y) if and only if all paths from Y to an exit block must pass through Z. Notions of immediate postdominance and a postdominator tree carry over.

Note that if a CFG has a single exit node, then postdominance is equivalent to dominance if flow is reversed (going from the exit node to the start node).
Control Flow Graph

Postdominator Tree
Dominance Frontiers

Dominators and postdominators tell us which basic block must be executed prior to, or after, a block N.

It is interesting to consider blocks “just before” or “just after” blocks we’re dominated by, or blocks we dominate.

The Dominance Frontier of a basic block N, DF(N), is the set of all blocks that are immediate successors to blocks dominated by N, but which aren’t themselves strictly domined by N.
DF(N) = 
{Z | M → Z & (N dom M) & 
¬(N sdom Z)}

The dominance frontier of N is the set of blocks that are not dominated N and which are “first reached” on paths from N.
Example

Control Flow Graph

<table>
<thead>
<tr>
<th>Block</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>E</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dominance</td>
<td>φ</td>
<td>{F}</td>
<td>{E}</td>
<td>{E}</td>
<td>{F}</td>
<td>φ</td>
</tr>
<tr>
<td>Frontier</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
A block can be in its own Dominance Frontier:

\[
\begin{array}{c}
A \\
\downarrow \\
B \\
\downarrow \\
C
\end{array}
\]

Here, DF(A) = \{A\}

Why? Reconsider the definition:

\[
DF(N) = \{Z \mid M \rightarrow Z \land (N \text{ dom } M) \land \neg(N \text{ sdom } Z)\}
\]

Now B is dominated by A and B→A.

Moreover, A does not strictly dominate itself. So, it meets the definition.
Postominance Frontiers

The Postominance Frontier of a basic block $N$, PDF($N$), is the set of all blocks that are immediate predecessors to blocks postdominated by $N$, but which aren’t themselves postdomined by $N$.

PDF($N$) =

\{ Z \mid Z \rightarrow M \; \& \; (N \; pdom \; M) \; \& \; 
\neg (N \; pdom \; Z) \}\n
The postdominance frontier of $N$ is the set of blocks closest to $N$ where a choice was made of whether to reach $N$ or not.
Example

Control Flow Graph

Postominator Tree

<table>
<thead>
<tr>

<td>{A}</td>
<td>{B}</td>
<td>{B}</td>
<td>{A}</td>
<td>φ</td>
</tr>
<tr>
<td>Frontier</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Control Dependence

Since CFGs model flow of control, it is useful to identify those Basic Blocks whose execution is controlled by a branch decision made by a Predecessor.

We say Y is control dependent on X if, reaching X, choosing one out arc will force Y to be reached, while choosing another arc out of X allows Y to be avoided.

Formally, Y is control dependent on X if and only if,

(a) Y postdominates a successor of X.
(b) Y does not postdominate all successors of X.

X is the most recent block where a choice was made to reach Y or not.
Control Dependence Graph

We can build a Control Dependence Graph that shows (in graphical form) all Control Dependence relations. (A Block can be Control Dependent on itself.)
What happened to H in the CD Graph?
Let’s reconsider the CD Graph:

Blocks C and F, as well as D and E, seem to have the same control dependence relations with their parent. But this isn’t so!

C and F are control equivalent, but D and E are mutually exclusive!
Improving the Representation of Control Dependence

We can label arcs in the CFG and the CD Graph with the condition (T or F or some switch value) that caused the arc to be selected for execution.

This labeling then shows the conditions that lead to the execution of a given block.

To allow the exit block to appear in the CD Graph, we can also add “artificial” start and exit blocks, linked together.
Now C and F have the same Control Dependence relations—they are part of the same extended basic block.

But D and E aren’t identically control dependent. Similarly, A and H are control equivalent, as are B and G.
Data Flow Frameworks Revisited

Recall that a Data Flow problem is characterized as:
(a) A Control Flow Graph
(b) A Lattice of Data Flow values
(c) A Meet operator to join solutions from Predecessors or Successors
(d) A Transfer Function
\[ \text{Out} = f_b(\text{In}) \text{ or } \text{In} = f_b(\text{Out}) \]
Value Lattice

The lattice of values is usually a meet semilattice defined by:

A: a set of values

T and ⊥ (“top” and “bottom”): distinguished values in the lattice

≤: A Reflexive Partial Order relating values in the Lattice

∧: An associative and commutative meet operator on lattice values
Lattice Axioms

The following axioms apply to the lattice defined by A, T, ⊥, ≤ and ∧:

\[ a \leq b \iff a \land b = a \]
\[ a \land a = a \]
\[ (a \land b) \leq a \]
\[ (a \land b) \leq b \]
\[ (a \land T) = a \]
\[ (a \land \bot) = \bot \]
Monotone Transfer Function

Transfer Functions, $f_b : L \rightarrow L$ (where $L$ is the Data Flow Lattice) are normally required to be monotone.
That is $x \leq y \Rightarrow f_b(x) \leq f_b(y)$.

This rule states that a “worse” input can’t produce a “better” output.

Monotone transfer functions allow us to guarantee that Data Flow solutions are stable.

If we had $f_b(T) = \bot$ and $f_b(\bot) = T$, then solutions might oscillate between $T$ and $\bot$ indefinitely.

Since $\bot \leq T$, $f_b(\bot)$ should be $\leq f_b(T)$.
But $f_b(\bot) = T$ which is not $\leq f_b(T) = \bot$. Thus $f_b$ isn’t monotone.
Dominator fit the Data Flow Framework

Given a set of Basic Blocks, N, we have:

A is $2^N$ (all subsets of Basic Blocks).

T is N.

⊥ is $\emptyset$.

$a \leq b \equiv a \subseteq b$.

$f_Z(\text{in}) = \text{In} \cup \{Z\}$

∧ is $\cap$ (set intersection).
The required axioms are satisfied:
\[ a \subseteq b \iff a \cap b = a \]
\[ a \cap a = a \]
\[ (a \cap b) \subseteq a \]
\[ (a \cap b) \subseteq b \]
\[ (a \cap \mathbb{N}) = a \]
\[ (a \cap \emptyset) = \emptyset \]

Also, \( f_\mathbb{Z} \) is monotone since
\[ a \subseteq b \Rightarrow a \cup \{Z\} \subseteq b \cup \{Z\} \Rightarrow f_\mathbb{Z}(a) \subseteq f_\mathbb{Z}(b) \]
Constant Propagation

We can model Constant Propagation as a Data Flow Problem. For each scalar integer variable, we will determine whether it is known to hold a particular constant value at a particular basic block.

The value lattice is

\[ T \]

\[ \ldots, -2, -1, 0, 1, 2, \ldots \]

\[ \bot \]

\[ T \] represents a variable holding a constant, whose value is not yet known.

\[ i \] represents a variable holding a known constant value.
\bot represents a variable whose value is non-constant.

This analysis is complicated by the fact that variables interact, so we can’t just do a series of independent one variable analyses.

Instead, the solution lattice will contain functions (or vectors) that map each variable in the program to its constant status (\(T\), \(\bot\), or some integer).

Let \(V\) be the set of all variables in a program.
Let $t : V \rightarrow N \cup \{T, \bot\}$

$t$ is the set of all total mappings from $V$ (the set of variables) to $N \cup \{T, \bot\}$ (the lattice of “constant status” values).

For example, $t_1 = (T, 6, \bot)$ is a mapping for three variables (call them $A$, $B$ and $C$) into their constant status. $t_1$ says $A$ is considered a constant, with value as yet undetermined. $B$ holds the value 6, and $C$ is non-constant.

We can create a lattice composed of $t$ functions:

$t_T(V) = T \ (\forall \ V) \ (t_T=(T,T,T, \ldots))$

$t_\bot(V) = \bot \ (\forall \ V) \ (t_\bot=(\bot,\bot,\bot, \ldots))$
\[ t_a \leq t_b \iff \forall v \ t_a(v) \leq t_b(v) \]

Thus \((1, \bot) \leq (T, 3)\)

since \(1 \leq T\) and \(\bot \leq 3\).

The meet operator \(\wedge\) is applied componentwise:

\[ t_a \wedge t_b = t_c \]

where \(\forall v \ t_c(v) = t_a(v) \wedge t_b(b)\)

Thus \((1, \bot) \wedge (T, 3) = (1, \bot)\)

since \(1 \wedge T = 1\) and \(\bot \wedge 3 = \bot\).
The lattice axioms hold:

\[ t_a \leq t_b \iff t_a \land t_b = t_a \] (since this axiom holds for each component)

\[ t_a \land t_a = t_a \] (trivially holds)

\[ (t_a \land t_b) \leq t_a \] (per variable def of \( \land \))

\[ (t_a \land t_b) \leq t_b \] (per variable def of \( \land \))

\[ (t_a \land t_T) = t_a \] (true for all components)

\[ (t_a \land t_\bot) = t_\bot \] (true for all components)
**The Transfer Function**

Constant propagation is a forward flow problem, so \( \text{Cout} = f_b(\text{Cin}) \)

\( \text{Cin} \) is a function, \( t(v) \), that maps variables to \( T, \bot, \) or an integer value

\( f_b(t(v)) \) is defined as:

1. Initially, let \( t'(v) = t(v) \) (\( \forall v \))
2. For each assignment statement 
   \( v = e(w_1, w_2, \ldots, w_n) \)
   in \( b \), in order of execution, do:
   - If any \( t'(w_i) = \bot \) (1 \( \leq i \leq n \))
     Then set \( t'(v) = \bot \) (strictness)
   - Elsif any \( t'(w_i) = T \) (1 \( \leq i \leq n \))
     Then set \( t'(v) = T \) (delay eval of \( v \))
   - Else \( t'(v) = e(t'(w_1), t'(w_2), \ldots) \)
3. \( \text{Cout} = t'(v) \)
Note that in valid programs, we don’t use uninitialized variables, so variables mapped to T should only occur prior to initialization.

Initially, all variables are mapped to T, indicating that initially their constant status is unknown.
Example

```
a=1
b=2

b=a+1
b=a+2

b=b-1
```

Flowchart:
- From `a=1 b=2`, go to `T, T`.
- From `T, T`, go to `a=1 b=2`.
- From `a=1 b=2`, go to `b=a+1`.
- From `b=a+1`, go to `b=a+2`.
- From `b=a+2`, go to `b=b-1`.
- From `b=b-1`, go to `b=b-1`.

Edges:
- `a=1 b=2` to `1,2`.
- `1,2` to `b=a+1`.
- `b=a+1` to `1,2`.
- `1,2` to `b=a+2`.
- `b=a+2` to `1,3`.
- `1,3` to `b=b-1`.
- `b=b-1` to `1,⊥`.
- `1,⊥` to `b=b-1`.
- `b=b-1` to `1,⊥`.
- `1,⊥` to `b=b-1`.

States:
- `a=1 b=2`.
- `b=a+1`.
- `b=a+2`.
- `b=b-1`.
- `T, T`.
- `1,2`.
- `1,3`.
- `⊥`.

Initial State:
- `a=1 b=2`.

Final States:
- `b=b-1`.
- `⊥`.
Distributive Functions

From the properties of $\land$ and $f$’s monotone property, we can show that
\[ f(a \land b) \leq f(a) \land f(b) \]
To see this note that
\[ a \land b \leq a, \quad a \land b \leq b \quad \Rightarrow \]
\[ f(a \land b) \leq f(a), \quad f(a \land b) \leq f(b) \quad (*) \]
Now we can establish that
\[ x \leq y, \quad x \leq z \quad \Rightarrow \quad x \leq y \land z \quad (**) \]
To see that (**) holds, note that
\[ x \leq y \quad \Rightarrow \quad x \land y = x \]
\[ x \leq z \quad \Rightarrow \quad x \land z = x \]
\[ (y \land z) \land x \leq y \land z \]
\[ (y \land z) \land x = (y \land z) \land (x \land x) = (y \land x) \land (z \land x) = x \land x = x \]
Thus $x \leq y \land z$, establishing (**).
Now substituting $f(a \land b)$ for $x$, $f(a)$ for $y$ and $f(b)$ for $z$ in (\*) and using (*) we get

$$f(a \land b) \leq f(a) \land f(b).$$

Many Data Flow problems have flow equations that satisfy the distributive property:

$$f(a \land b) = f(a) \land f(b)$$

For example, in our formulation of dominators:

$$\text{Out} = f_b(\text{In}) = \text{In} \cup \{b\}$$

where

$$\text{In} = \bigcap_{p \in \text{Pred}(b)} \text{Out}(p)$$
In this case, $\land = \cap$.

Now $f_b(S_1 \cap S_2) = (S_1 \cap S_2) \cup \{b\}$

Also, $f_b(S_1) \cap f_b(S_2) =$

$$(S_1 \cup \{b\}) \cap (S_2 \cup \{b\}) =$$

$$(S_1 \cap S_2) \cup \{b\}$$

So dominators are distributive.
Not all Data Flow Problems are Distributive

Constant propagation is not distributive.

Consider the following (with variables \((x,y,z)\)):

\[
t_1 = (T,1,3) \quad \text{and} \quad t_2 = (T,2,2)
\]

\[
x = y + z
\]

Now \(f(t) = t'\) where

\[
t'(y) = t(y), \quad t'(z) = t(z),
\]

\[
t'(x) = \begin{cases} 
\bot & \text{if } t(y) = \bot \text{ or } t(z) = \bot \\
\text{T} & \text{if } t(y) = \text{T} \text{ or } t(z) = \text{T} \\
\text{T} & \text{else}
\end{cases}
\]

\[
t'(y) + t(z)
\]
Now $f(t_1 \land t_2) = f(T, \bot, \bot) = (\bot, \bot, \bot)$

$f(t_1) = (4, 1, 3)$

$f(t_2) = (4, 2, 2)$

$f(t_1) \land f(t_2) = (4, \bot, \bot) \geq (\bot, \bot, \bot)$
Why does it Matter if a Data Flow Problem isn’t Distributive?

Consider actual program execution paths from \( b_0 \) to (say) \( b_k \).

One path might be \( b_0, b_{i_1}, b_{i_2}, \ldots, b_{i_n} \)
where \( b_{i_n} = b_k \).

At \( b_k \) the Data Flow information we want is
\[
 f_{i_n}(...f_{i_2}(f_{i_1}(f_0(T)))... ) \equiv f(b_0, b_1, \ldots, b_{i_n})
\]

On a different path to \( b_k \), say
\( b_0, b_{j_1}, b_{j_2}, \ldots, b_{j_m} \)
where \( b_{j_m} = b_k \)

the Data Flow result we get is
\[
 f_{j_m}(...f_{j_2}(f_{j_1}(f_0(T)))... ) \equiv 
 f(b_0, b_{j_1}, \ldots, b_{j_m}).
\]
Since we can’t know at compile time which path will be taken, we must combine all possible paths:

\[ \bigwedge_{p \in \text{all paths to } b_k} f(p) \]

This is the meet over all paths (MOP) solution. It is the best possible static solution. (Why?)

As we shall see, the meet over all paths solution can be computed efficiently, using standard Data Flow techniques, if the problem is Distributive.

Other, non-distributive problems (like Constant Propagation) can’t be solved as precisely.

Explicitly computing and meeting all paths is prohibitively expensive.

Conditional Constant Propagation

We can extend our Constant Propagation Analysis to determine that some paths in a CFG aren’t executable. This is Conditional Constant Propagation.

Consider

\[
i = 1; \\
\text{if } (i > 0) \\
\quad j = 1; \\
\text{else } j = 2;
\]

Conditional Constant Propagation can determine that the else part of the if is unreachable, and hence \( j \) must be 1.
The idea behind Conditional Constant Propagation is simple. Initially, we mark all edges out of conditionals as “not reachable.”

Starting at $b_0$, we propagate constant information only along edges considered reachable.

When a boolean expression $b(v_1,v_2,...)$ controls a conditional branch, we evaluate $b(v_1,v_2,...)$ using the $t(v)$ mapping that identifies the “constant status” of variables.

If $t(v_i)=T$ for any $v_i$, we consider all out edges unreachable (for now). Otherwise, we evaluate $b(v_1,v_2,...)$ using $t(v)$, getting true, false or $\bot$. 
Note that the short-circuit properties of boolean operators may yield true or false even if $t(v_i)=\bot$ for some $v_i$.

If $b(v_1, v_2, \ldots)$ is true or false, we mark only one out edge as reachable. Otherwise, if $b(v_1, v_2, \ldots)$ evaluates to $\bot$, we mark all out edges as reachable. We propagate constant information only along reachable edges.
Example

```c
i = 1;
done = 0;
while ( i > 0 && ! done) {
  if (i == 1)
    done = 1;
  else i = i + 1;
}
```

(T,T) = (i,done)
Pass 1:

\[
\begin{array}{c}
i = 1; \\
done = 0;
\end{array}
\]

\[
\begin{array}{c}
i > 0 \land \neg done \\
\end{array}
\]

\[
\begin{array}{c}
i == 1 \\
\end{array}
\]

\[
\begin{array}{c}
i = i + 1; \\
\end{array}
\]

\[
\begin{array}{c}
done = 1; \\
\end{array}
\]

\[
(T,T) = (i,done)
\]

(1,0) → T → (1,0) → F → (1,0) → T → (1,1)

(1,0) → T → (1,1)

(1,1)
Pass 2:

\[ i = 1; \]
\[ \text{done} = 0; \]

\[ (1,0) \]

\[ i > 0 \land \neg \text{done} \]

\[ (1,\bot) \]

\[ i = i + 1; \]

\[ (1,1) \]

\[ \text{done} = 1; \]

\[ (1,1) \]

\[ (T,T) = (i,\text{done}) \]

Tuesday, November 27,
Professor Tom Reps,
“Program Analysis via Graph Reachability”
Iterative Solution of Data Flow Problems

This algorithm will use DFO numbering to determine the order in which blocks are visited for evaluation. We iterate over the nodes until convergence.
EvalDF{
    For (all n ∈ CFG) {
        soln(n) = T
        ReEval(n) = true }
    Repeat
        LoopAgain = false
        For (all n ∈ CFG in DFO order) {
            If (ReEval(n)) {
                ReEval(n) = false
                OldSoln = soln(n)
                In = \bigwedge_{p ∈ Pred(n)} soln(p)
                soln(n) = f_n(In)
                If (soln(n) ≠ OldSoln) {
                    For (all s ∈ Succ(n)) {
                        ReEval(s) = true
                        LoopAgain = LoopAgain OR IsBackEdge(n,s)
                    } }
            } }
        Until (! LoopAgain)
Example: Reaching Definitions
We’ll do this as a set-valued problem (though it really is just three bit-valued analyses, since each analysis is independent).

$L$ is the power set of Basic Blocks

$\land$ is set union

$T$ is $\emptyset$; $\bot$ is the set of all blocks

$a \leq b \equiv b \subseteq a$

$f_3(in) = \{3\}$

$f_6(in) = \{6\}$

$f_7(in) = \{7\}$

For all other blocks, $f_b(in) = in$
We’ll track soln and ReEval across multiple passes

Properties of Iterative Data Flow Analysis

• If the height of the lattice (the maximum distance from $T$ to $\bot$) is finite, then termination is guaranteed. Why?
Recall that transfer functions are assumed monotone ($a \leq b \Rightarrow f(a) \leq f(b)$). Also, $\wedge$ has the property that $a \wedge b \leq a$ and $a \wedge b \leq b$.
At each iteration, some solution value must change, else we halt. If something changes it must “move down” the lattice (we start at $T$). If the lattice has finite height, each block’s value can change only a bounded number of times. Hence termination is guaranteed.
• If the iterative data flow algorithm terminates, a valid solution must have been computed. (This is because data flow values flow forward, and any change along a backedge forces another iteration.)
How Many Iterations are Needed?

Can we bound the number of iterations needed to compute a data flow solution?

In our example, 3 passes were needed, but why?

In an “ideal” CFG, with no loops or backedges, only 1 pass is needed.

With backedges, it can take several passes for a value computed in one block to reach a block that depends upon the value.
Let \( p \) be the maximum number of backedges in any acyclic path in the CFG.

Then \( (p+1) \) passes suffice to propagate a data flow value to any other block that uses it.

Recall that any block’s value can change only a bounded number of times. In fact, the height of the lattice (maximum distance from top to bottom) is that bound.

Thus the maximum number of passes in our iterative data flow evaluator = 
\[(p+1) \times \text{Height of Lattice}\]

In our example, \( p = 2 \) and lattice height really was 1 (we did 3 independent bit valued problems).

So passes needed = \((2+1) * 1 = 3\).
Rapid Data Flow Frameworks

We still have the concern that it may take many passes to traverse a Solution Lattice that has a significant height.

Many data flow problems are rapid. For rapid data flow problems, extra passes to feed back values along cyclic paths aren’t needed.

For a data flow problem to be rapid we require that:

\[
(\forall a \in A)(\forall f \in F) \quad a \land f(T) \leq f(a)
\]
This is an odd requirement that states that using \( f(T) \) as a very crude approximation to a value computed by \( F \) is OK when joined using the \( \land \) operator. In effect the term "a" rather than \( f(T) \) is dominant).

(Recall that \( a \land f(a) \leq f(a) \) always holds.)
How does the Rapid Data Flow Property Help?

Consider a direct feedback loop (the idea holds for indirect loops too):

\[ f \]

\[ a \]

a is an input from outside the loop. Our concern is how often we’ll need to reevaluate f, as new values are computed and fed back into f. Initially, we’ll use T to model the value on the backedge.
Iteration 1: Input = a ∧ T = a
   Output = f(a)
Iteration 2: Input = a ∧ f(a)
   Output = f(a ∧ f(a))
Iteration 3: Input = a ∧ f(a ∧ f(a))

Now we’ll exploit the rapid data flow property: b ∧ f(T) ≤ f(b)
Let b ≡ a ∧ f(a)
Then a ∧ f(a) ∧ f(T) ≤ f(a ∧ f(a)) (*)
Note that x ≤ y ⇒ a ∧ x ≤ a ∧ y (**)
To prove this, recall that
   (1) p ∧ q = p ⇒ p ≤ q
   (2) x ≤ y ⇒ x ∧ y = x
Thus (a ∧ x) ∧ (a ∧ y) = a ∧ (x ∧ y) = (a ∧ x) (by 2) ⇒ (a ∧ x) ≤ (a ∧ y) (by 1).
From (*) and (**) we get
\[ a \land a \land f(a) \land f(T) \leq f(a \land f(a)) \land a \] (***)
Now \( a \leq T \Rightarrow f(a) \leq f(T) \Rightarrow f(a) \land f(T) = f(a). \)
Using this on (***), we get
\[ a \land f(a) \leq f(a \land f(a)) \land a \]
That is, \( \text{Input}_2 \leq \text{Input}_3 \)
Note too that
\[ a \land f(a) \leq a \Rightarrow f(a \land f(a)) \leq f(a) \Rightarrow a \land f(a \land f(a)) \leq a \land f(a) \]
That is, \( \text{Input}_3 \leq \text{Input}_2 \)
Thus we conclude \( \text{Input}_2 = \text{Input}_3 \), which means we can stop after two passes independent of lattice height!
(One initial visit plus one reevaluation via the backedge.)
Many Important Data Flow Problems are Rapid

Consider reaching definitions, done as sets. We may have many definitions to the same variable, so the height of the lattice may be large.

$L$ is the power set of Basic Blocks

$\land$ is set union

$T$ is $\emptyset$; $\perp$ is the set of all blocks

$a \leq b \equiv a \supseteq b$

$f_b(in) = (In - Kill_b) \cup Gen_b$

where $Gen_b$ is the last definition to a variable in $b$,

$Kill_b$ is all defs to a variable except the last one in $b$, 

Kill_b is empty if there is no def to a variable in b.

The Rapid Data Flow Property is

\[ a \land f(T) \leq f(a) \]

In terms of Reaching Definitions this is

\[ a \cup f(\phi) \supseteq f(a) \equiv \]

\[ a \cup (\phi - \text{Kill}) \cup \text{Gen} \supseteq (a - \text{Kill}) \cup \text{Gen} \]

Simplifying,

\[ a \cup \text{Gen} \supseteq (a - \text{Kill}) \cup \text{Gen} \]

which always holds.
Recall

Here it took two passes to transmit the def in b7 to b1, so we expect 3 passes to evaluate independent of the lattice height.
Constant Propagation isn't Rapid

We require that

\[ a \land f(T) \leq f(a) \]

Consider

\[
\begin{align*}
  & i=1 \\
  & j=1 \\
  & k=1 \\
\end{align*}
\]

\[
\begin{align*}
  & k=j \\
  & j=i \\
  & i=2 \\
\end{align*}
\]

Look at the transfer function for the second (bottom) block.
\[ f(t) = t' \text{ where} \]

\[
t'(v) = \text{case}(v) \{
    \text{k: } t(j);
    \text{j: } t(i);
    \text{i: } 2;
}\]

Let \( a = (\bot,1,1) \).

\[ f(T) = (2,T,T) \]

\[ a \land f(T) = (\bot,1,1) \land (2,T,T) = (\bot,1,1) \]

\[ f(a) = f(\bot,1,1) = (2,\bot,1). \]

Now \((\bot,1,1)\) is not \(\leq (2,\bot,1)\)

so this problem isn't rapid.
Let’s follow the iterations:

Pass 1: $\text{In} = (1,1,1) \land (T,T,T) = (1,1,1)$
Out = (2,1,1)

Pass 2: $\text{In} = (1,1,1) \land (2,1,1) = (\bot,1,1)$
Out = (2,\bot,1)

Pass 3: $\text{In} = (1,1,1) \land (2,\bot,1) = (\bot,\bot,1)$
Out = (2,\bot,\bot)

This took 3 passes. In general, if we had $N$ variables, we could require $N$ passes, with each pass resolving the constant status of one variable.
Reading Assignment

Read “An Efficient Method of Computing Static Single Assignment Form.”
(Linked from the class Web page.)
How Good Is Iterative Data Flow Analysis?

A single execution of a program will follow some path 
\( b_0, b_1, b_2, \ldots, b_n. \)

The Data Flow solution along this path is 
\[ f_{i_n}(\ldots f_{i_2}(f_{i_1}(f_0(T)))\ldots) \equiv f(b_0, b_1, \ldots, b_n) \]

The best possible static data flow solution at some block \( b \) is computed over all possible paths from \( b_0 \) to \( b \).

Let \( P_b = \) The set of all paths from \( b_0 \) to \( b \).

\[ \text{MOP}(b) = \bigwedge_{p \in P_b} f(p) \]
Any particular path $p_i$ from $b_0$ to $b$ is included in $P_b$.

Thus $\text{MOP}(b) \land f(p_i) = \text{MOP}(b) \leq f(p_i)$.

This means $\text{MOP}(b)$ is always a safe approximation to the “true” solution $f(p_i)$. 
If we have the distributive property for transfer functions,
\[ f(a \land b) = f(a) \land f(b) \]
then our iterative algorithm always computes the MOP solution, the best static solution possible.

To prove this, note that for trivial path of length 1, containing only the start block, \( b_0 \), the algorithm computes \( f_0(T) \) which is MOP\( (b_0) \) (trivially).

Now assume that the iterative algorithm for paths of length \( n \) or less to block \( c \) does compute MOP\( (c) \).

We’ll show that for paths to block \( b \) of length \( n+1 \), MOP\( (b) \) is computed.

Let \( P \) be the set of all paths to \( b \) of length \( n+1 \) or less.
The paths in $P$ end with $b$.

$\text{MOP}(b) = f_b(f(P_1)) \land f_b(f(P_2)) \land \ldots$

where $P_1$, $P_2$, $\ldots$ are the prefixes (of length $n$ or less) of paths in $P$ with $b$ removed.

Using the distributive property,

$f_b(f(P_1)) \land f_b(f(P_2)) \land \ldots = f_b(f(P_1) \land f(P_2) \land \ldots)$.

But note that $f(P_1) \land f(P_2) \land \ldots$ is just the input to $f_b$ in our iterative algorithm, which then applies $f_b$.

Thus $\text{MOP}(b)$ for paths of length $n+1$ is computed.
For data flow problems that aren’t distributive (like constant propagation), the iterative solution is \( \leq \) the MOP solution.

This means that the solution is a safe approximation, but perhaps not as “sharp” as we might wish.
Exploiting Structure in Data Flow Analysis

So far we haven’t utilized the fact that CFGs are constructed from standard programming language constructs like IFs, Fors, and Whiles. Instead of iterating across a given CFG, we can isolate, and solve symbolically, subgraphs that correspond to “standard” programming language constructs. We can then progressively simplify the CFG until we reach a single node, or until we reach a CFG structure that matches no standard pattern. In the latter case, we can solve the residual graph using our iterative evaluator.
Three Program-Building Operations

1. Sequential Execution (";")
2. Conditional Execution (If, Switch)
3. Iterative Execution (While, For, Repeat)
Sequential Execution

We can reduce a sequential “chain” of basic blocks:

\[ b_1 \rightarrow b_2 \rightarrow \cdots \rightarrow b_n \]

into a single composite block:

\[ b_{seq} \]

The transfer function of \( b_{seq} \) is

\[ f_{seq} = f_n \circ f_{n-1} \circ \ldots \circ f_1 \]

where \( \circ \) is functional composition.
Conditional Execution

Given the basic blocks:

\[ b_p \]

\[ b_{L1} \quad b_{L2} \]

we create a single composite block:

\[ b_{\text{cond}} \]

The transfer function of \( b_{\text{cond}} \) is

\[ f_{\text{cond}} = f_{L1} \circ f_p \land f_{L2} \circ f_p \]
Iterative Execution

Repeat Loop

Given the basic blocks:

\[ b_B \]

\[ b_C \]

we create a single composite block:

\[ b_{\text{repeat}} \]

Here \( b_B \) is the loop body, and \( b_C \) is the loop control.
If the loop iterates once, the transfer function is $f_C \circ f_B$.

If the loop iterates twice, the transfer function is $(f_C \circ f_B) \circ (f_C \circ f_B)$.

Considering all paths, the transfer function is $(f_C \circ f_B) \land (f_C \circ f_B)^2 \land \ldots$

Define $\text{fix } f \equiv f \land f^2 \land f^3 \land \ldots$

The transfer function of repeat is then

$$f_{\text{repeat}} = \text{fix}(f_C \circ f_B)$$
**While Loop.**

Given the basic blocks:

```
  b_C
 /   \
 v    v
 b_B
     ^
     v
 b_while
```

we create a single composite block:

Here again $b_B$ is the loop body, and $b_C$ is the loop control.

The loop always executes $b_C$ at least once, and always executes $b_C$ as the last block before exiting.
The transfer function of a while is therefore

\[ f_{\text{while}} = f_{C} \land \text{fix}(f_{C} \circ f_{B}) \circ f_{C} \]
Evaluating Fixed Points

For lattices of height \( H \), and monotone transfer functions, \( \text{fix } f \) needs to look at no more than \( H \) terms.

In practice, we can give \( \text{fix } f \) an operational definition, suitable for implementation:

Evaluate

\[
(\text{fix } f)(x) \{
    \text{prev} = \text{soln} = f(x);
    \text{while } (\text{prev} \neq \text{new} = f(\text{prev}))\{
        \text{prev} = \text{new};
        \text{soln} = \text{soln} \land \text{new};
    \}
    \text{return } \text{soln};
\}
\]
The transfer functions are either constant-valued \((f_1=\{b_1\}, f_4=\{b_4\}, f_5=\{b_5\})\) or identity functions \((f_2=f_3=f_6=f_7=\text{Id})\).
First we isolate and reduce the conditional:

\[ f_C = f_4 \circ f_3 \land f_5 \circ f_3 = \{b4\} \circ \text{Id} \cup \{b5\} \circ \text{Id} = \{b4, b5\} \]
Substituting, we get

\[ f_6 \circ f_C = \text{Id} \circ f_C = f_C \]
We now have

We isolate and reduce the while loop formed by $b_2$ and $b_C$, creating $b_W$.

The transfer function is

$$f_W = f_2 \land (\text{fix}(f_2 \circ f_C) \circ f_2 =$$

$$\text{Id U (fix(Id o f_C ) o Id) =}$$

$$\text{Id U (fix(f_C)) =}$$

$$\text{Id U (f_C \land f_C^2 \land f_C^3 \land \ldots) =}$$

$$\text{Id U \{b4,b5\} }$$
We now have

\[
\begin{array}{c}
\text{X} \leftarrow 1 \\
W \\
7
\end{array}
\]

We compose these three sequential blocks to get the whole solution, \( f_P \).

\[
f_P = \text{Id} \circ (\text{Id} \cup \{f_4,f_5\}) \circ \{b_1\} = \{b_1,b_4,b_5\}.
\]

These are the definitions that reach the end of the program.

We can expand subgraphs to get the solutions at interior blocks.
Thus at the beginning of the while, the solution is \{b1\}.

At the head if the If, the solution is

\[(\text{Id} \cup (\text{Id} \circ f_C \circ \text{Id}) \cup (\text{Id} \circ f_C \circ \text{Id} \circ f_C \circ \text{Id}) \cup \ldots )({\{b1}\}) = \{b1\} \cup \{b4,b5\} \cup \{b4,b5\} \cup \ldots = \{b1,b4,b5\}\]

At the head of the then part of the If, the solution is \text{Id}(\{b1,b4,b5\}) = \{b1,b4,b5\}.
Static Single Assignment Form

Many of the complexities of optimization and code generation arise from the fact that a given variable may be assigned to in many different places.

Thus reaching definition analysis gives us the set of assignments that may reach a given use of a variable.

Live Range Analysis must track all assignments that may reach a use of a variable and merge them into the same live range.

Available Expression Analysis must look at all places a variable may be assigned to and decide if any kill an already computed expression.
What If

Each variable is assigned to in only one place? (Much like a named constant).

Then for a given use, we can find a single unique definition point.

But this seems impossible for most programs—or is it?

In Static Single Assignment (SSA) Form each assignment to a variable, v, is changed into a unique assignment to new variable, vᵢ.

If variable v has n assignments to it throughout the program, then (at least) n new variables, v₁ to vₙ, are created to replace v. All uses of v are replaced by a use of some vᵢ.
Phi Functions

Control flow can’t be predicted in advance, so we can’t always know which definition of a variable reached a particular use.

To handle this uncertainty, we create phi functions.

As illustrated below, if $v_i$ and $v_j$ both reach the top of the same block, we add the assignment

$$v_k \leftarrow \phi(v_i, v_j)$$

to the top of the block.

Within the block, all uses of $v$ become uses of $v_k$ (until the next assignment to $v$).
What does $\phi(v_i,v_j)$ Mean?

One way to read $\phi(v_i,v_j)$ is that if control reaches the phi function via the path on which $v_i$ is defined, $\phi$ "selects" $v_i$; otherwise it "selects" $v_j$.

Phi functions may take more than 2 arguments if more than 2 definitions might reach the same block.

Through phi functions we have simple links to all the places where $v$ receives a value, directly or indirectly.
Example

Original CFG

CFG in SSA Form
In SSA form computing live ranges is almost trivial. For each $x_i$ include all $x_j$ variables involved in phi functions that define $x_i$.

Initially, assume $x_1$ to $x_6$ (in our example are independent). We then union into equivalence classes $x_i$ values involved in the same phi function or assignment.

Thus $x_1$ to $x_3$ are unioned together (forming a live range). Similarly, $x_4$ to $x_6$ are unioned to form a live range.
CS 701 Final Exam

Tuesday, December 18, 10 a.m.—noon, 1325 Computer Sciences Bldg.

Guest Lecture

Thursday, December 6,
Professor Ras Bodik,
“Path Sensitive Value-Flow Optimizations”
Constant Propagation in SSA

In SSA form, constant propagation is simplified since values flow directly from assignments to uses, and phi functions represent natural “meet points” where values are combined (into a constant or ⊥).

Even conditional constant propagation fits in. As long as a path is considered unreachable, it variables are set to T (and therefore ignored at phi functions, which meet values together).
Example

\[
\begin{align*}
\text{Pass 1:} & \\
& \text{repeat}
\end{align*}
\]

\[
\begin{align*}
& \text{if } (i==6) \\
& \quad k = 0 \\
& \text{else} \\
& \quad i = i + 1 \\
& \quad i = i + k \\
& \quad j = j + 1 \\
& \text{until } (i==j)
\end{align*}
\]

\[
\begin{align*}
\text{Pass 2:} & \\
& \text{repeat}
\end{align*}
\]

\[
\begin{align*}
& \text{if } (i_2==6) \\
& \quad k_3 = 0 \\
& \text{else} \\
& \quad i_3 = i_2 + 1 \\
& \quad i_4 = \phi(i_2, i_3) \\
& \quad k_4 = \phi(k_3, k_2) \\
& \quad i_5 = i_4 + k_4 \\
& \quad j_3 = j_2 + 1 \\
& \text{until } (i_5==j_3)
\end{align*}
\]

<table>
<thead>
<tr>
<th></th>
<th>$i_1$</th>
<th>$j_1$</th>
<th>$k_1$</th>
<th>$i_2$</th>
<th>$j_2$</th>
<th>$k_2$</th>
<th>$k_3$</th>
<th>$i_3$</th>
<th>$i_4$</th>
<th>$k_4$</th>
<th>$i_5$</th>
<th>$j_3$</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Pass 1</strong></td>
<td>6</td>
<td>1</td>
<td>1</td>
<td>6 $\land$ T</td>
<td>1 $\land$ T</td>
<td>1 $\land$ T</td>
<td>0</td>
<td>T</td>
<td>6 $\land$ T</td>
<td>0</td>
<td>6</td>
<td>2</td>
</tr>
<tr>
<td><strong>Pass 2</strong></td>
<td>6</td>
<td>1</td>
<td>1</td>
<td>6 $\land$ 6</td>
<td>$\perp$</td>
<td>$\perp$</td>
<td>0</td>
<td>T</td>
<td>6</td>
<td>0</td>
<td>6</td>
<td>$\perp$</td>
</tr>
</tbody>
</table>

We have determined that $i = 6$ everywhere.
Putting Programs into SSA Form

Assume we have the CFG for a program, which we want to put into SSA form. We must:

- Rename all definitions and uses of variables
- Decide where to add phi functions

Renaming variable definitions is trivial—each assignment is to a new, unique variable.

After phi functions are added (at the heads of selected basic blocks), only one variable definition (the most recent in the block) can reach any use. Thus renaming uses of variables is easy.
Placing Phi Functions

Let b be a block with a definition to some variable, v. If b contains more than one definition to v, the last (or most recent) applies.

What is the first basic block following b where some other definition to v as well as b’s definition can reach?

In blocks dominated by b, b’s definition must have been executed, though other later definitions may have overwritten b’s definition.
Domination Frontiers (Again)

Recall that the Domination Frontier of a block b, is defined as

$$DF(N) = \{ Z | M \rightarrow Z \& (N \text{ dom } M) \& \neg(N \text{ sdom } Z) \}$$

The Dominance Frontier of a basic block N, DF(N), is the set of all blocks that are immediate successors to blocks dominated by N, but which aren’t themselves strictly dominated by N.

Assume that an initial assignment to all variables occurs in b₀ (possibly of some special “uninitialized value.”)
We will need to place a phi function at the start of all blocks in b’s Domination Frontier.

The phi functions will join the definition to v that occurred in b (or in a block dominated by v) with definitions occurring on paths that don’t include b.

After phi functions are added to blocks in DF(b), the domination frontier of blocks with newly added phi’s will need to be computed (since phi functions imply assignment to a new $v_i$ variable).
Examples of How Domination Frontiers Guide Phi Placement

\[ \text{DF}(N) = \{ Z \mid M \rightarrow Z \land (N \text{ dom } M) \land \neg(N \text{ sdom } Z) \} \]

Simple Case:

Here, (N dom M) but \( \neg(N \text{ sdom } Z) \), so a phi function is needed in Z.
Loop:

Here, let $M = Z = N$. $M \rightarrow Z$, (N dom M) but $\neg (N \text{ sdom } Z)$, so a phi function is needed in $Z$. 

$DF(N) = 
\{ Z \mid M \rightarrow Z \text{ & (N dom M) & } \neg (N \text{ sdom } Z) \}$
Sometimes Phi's must be Placed Iteratively

Now, DF(b1) = {b3}, so we add a phi function in b3. This adds an assignment into b3. We then look at DF(b3) = {b5}, so another phi function must be added to b5.
Phi Placement Algorithm

To decide what blocks require a phi function to join a definition to a variable \( v \) in block \( b \):

1. Compute \( D_1 = DF(b) \).
   Place Phi functions at the head of all members of \( D_1 \).

2. Compute \( D_2 = DF(D_1) \).
   Place Phi functions at the head of all members of \( D_2 - D_1 \).

3. Compute \( D_3 = DF(D_2) \).
   Place Phi functions at the head of all members of \( D_3 - D_2 - D_1 \).

4. Repeat until no additional Phi functions can be added.
PlacePhi{
    For (each variable \( v \in \text{program} \) ){
        For (each block \( b \in \text{CFG} \) ){
            \( \text{PhiInserted}(b) = \text{false} \)
            \( \text{Added}(b) = \text{false} \)
        }
        \( \text{List} = \emptyset \)
        For (each \( b \in \text{CFG} \) that assigns to \( V \) ){
            \( \text{Added}(b) = \text{true} \)
            \( \text{List} = \text{List} \cup \{ b \} \)
        }
        While (\( \text{List} \neq \emptyset \)) {
            Remove any \( b \) from \( \text{List} \)
            For (each \( d \in \text{DF}(b) \) ){
                If (! \( \text{PhiInserted}(d) \) ) {
                    Add a Phi Function to \( d \)
                    \( \text{PhiInserted}(d) = \text{true} \)
                    If (! \( \text{Added}(d) \) ) {
                        \( \text{Added}(d) = \text{true} \)
                        \( \text{List} = \text{List} \cup \{ d \} \)
                    }
                }
            }
        }
    }
}
We will add Phi’s into blocks 4 and 5. The arity of each phi is the number of

Initially, List={1,3,5,6}

Process 1: DF(1) = φ

Process 3: DF(3) = 4, so add 4 to List and add phi fct to 4.

Process 5: DF(5)= {4,5} so add phi fct to 5.

Process 5: DF(6) = {5}

Process 4: DF(4) = {4}
in-arcs to its block. To find the args to a phi, follow each arc “backwards” to the sole reaching def on that path.
\[ x_1 = 1 \]

\[ x_2 = 2 \]

\[ x_5 = \phi(x_1, x_2, x_3) \]

\[ x_6 = \phi(x_4, x_5) \]

\[ x_3 = 3 \]

\[ x_4 = 4 \]
SSA and Value Numbering

We already know how to do available expression analysis to determine if a previous computation of an expression can be reused.

A limitation of this analysis is that it can’t recognize that two expressions that aren’t syntactically identical may actually still be equivalent.

For example, given

\[
\begin{align*}
t_1 &= a + b \\
c &= a \\
t_2 &= c + b
\end{align*}
\]

Available expression analysis won’t recognize that \( t_1 \) and \( t_2 \) must be equivalent, since it doesn’t track the fact that \( a = c \) at \( t_2 \).
Value Numbering

An early expression analysis technique called value numbering worked only at the level of basic blocks. The analysis was in terms of “values” rather than variable or temporary names.

Each non-trivial (non-copy) computation is given a number, called its value number.

Two expressions, using the same operators and operands with the same value numbers, must be equivalent.
For example,
\[
\begin{align*}
  t_1 &= a + b \\
  c &= a \\
  t_2 &= c + b \\
\end{align*}
\]
is analyzed as
\[
\begin{align*}
  v_1 &= a \\
  v_2 &= b \\
  t_1 &= v_1 + v_2 \\
  c &= v_1 \\
  t_2 &= v_1 + v_2 \\
\end{align*}
\]
Clearly $t_2$ is equivalent to $t_1$ (and hence need not be computed).
In contrast, given
\[ t_1 = a + b \]
\[ a = 2 \]
\[ t_2 = a + b \]
the analysis creates
\[ v_1 = a \]
\[ v_2 = b \]
\[ t_1 = v_1 + v_2 \]
\[ v_3 = 2 \]
\[ t_2 = v_3 + v_2 \]

Clearly \( t_2 \) is not equivalent to \( t_1 \) (and hence will need to be recomputed).
Extending Value Numbering to Entire CFGs

The problem with a global version of value numbering is how to reconcile values produced on different flow paths. But this is exactly what SSA is designed to do!

In particular, we know that an ordinary assignment

\[ x = y \]

does not imply that all references to \( x \) can be replaced by \( y \) after the assignment. That is, an assignment is not an assertion of value equivalence.
But, in SSA form

\[ x_i = y_j \]

does mean the two values are always equivalent after the assignment. If \( y_j \) reaches a use of \( x_i \), that use of \( x_i \) can be replaced with \( y_j \).

Thus in SSA form, an assignment is an assertion of value equivalence.
We will assume that simple variable to variable copies are removed by substituting equivalent SSA names. This alone is enough to recognize some simple value equivalences.

As we saw,

\[ t_1 = a_1 + b_1 \]
\[ c_1 = a_1 \]
\[ t_2 = c_1 + b_1 \]

becomes

\[ t_1 = a_1 + b_1 \]
\[ t_2 = a_1 + b_1 \]
Partitioning SSA Variables

Initially, all SSA variables will be partitioned by the form of the expression assigned to them. Expressions involving different constants or operators won’t (in general) be equivalent, even if their operands happen to be equivalent.

Thus

\[ v_1 = 2 \text{ and } w_1 = a_2 + 1 \]

are always considered inequivalent.

But,

\[ v_3 = a_1 + b_2 \text{ and } w_1 = d_1 + e_2 \]

may possibly be equivalent since both involve the same operator.
Phi functions are potentially equivalent only if they are in the same basic block.

All variables are initially considered equivalent (since they all initially are considered uninitialized until explicit initialization).

After SSA variables are grouped by assignment form, groups are split. If \( a_i \) \( \text{op} \) \( b_y \) and \( c_k \) \( \text{op} \) \( d_l \) are in the same group (because they both have the same operator, \( \text{op} \)) and \( a_i \not\equiv c_k \) or \( b_j \not\equiv d_l \), then we split the two expressions apart into different groups.

We continue splitting based on operand inequivalence, until no more splits are possible. Values still grouped are equivalent.
Example

if (...) {
    a_1=0
    if (...) b_1=0
    else {
        a_2=x_0
        b_2=x_0
    }
    a_3=\phi(a_1,a_2)
    b_3=\phi(b_1,b_2)
    c_2=\ast a_3
    d_2=\ast b_3
} else {
    b_4=10
} a_5=\phi(a_0,a_3)
 b_5=\phi(b_3,b_4)
 c_3=\ast a_5
 d_3=\ast b_5
 e_3=\ast a_5

Initial Groupings:

G_1=[a_0,b_0,c_0,d_0,e_0,x_0] 
G_2=[a_1=0,b_1=0] 
G_3=[a_2=x_0,b_2=x_0] 
G_4=[b_4=10] 
G_5=[a_3=\phi(a_1,a_2), b_3=\phi(b_1,b_2)] 
G_6=[a_5=\phi(a_0,a_3), b_5=\phi(b_3,b_4)] 
G_7=[c_2=\ast a_3, d_2=\ast b_3, d_3=\ast b_5, c_3=\ast a_5, e_3=\ast a_5] 

Now b_4 isn’t equivalent to anything, so split a_5 and b_5. In G_7 split operands b_3, a_5 and b_5. We now have
if (...) {
    a₁=0
    if (...) 
    b₁=0 
else {
    a₂=x₀ 
    b₂=x₀ }
    a₃=\phi(a₁, a₂)
    b₃=\phi(b₁, b₂)
    c₂=*a₃
    d₂=*b₃ }
else {
    b₄=10 }
    a₅=\phi(a₀, a₃)
    b₅=\phi(b₃, b₄)
    c₃=*a₅
    d₃=*b₅
    e₃=*a₅

Final Groupings:
G₁=[a₀, b₀, c₀, d₀, e₀, x₀]
G₂=[a₁=0, b₁=0]
G₃=[a₂=x₀, b₂=x₀]
G₄=[b₄=10]
G₅=[a₃=\phi(a₁, a₂),
     b₃=\phi(b₁, b₂)]
G₆a=[a₅=\phi(a₀, a₃)]
G₆b=[b₅=\phi(b₃, b₄)]
G₇a=[c₂=*a₃,
     d₂=*b₃]
G₇b=[d₃=*b₅]
G₇c=[c₃=*a₅,
     e₃=*a₅]

Variable e₃ can use c₃’s value and d₂ can use c₂’s value.
Limitations of Global Value Numbering

As presented, our global value numbering technique doesn't recognize (or handle) computations of the same expression that produce different values along different paths.

Thus in

\[
\begin{align*}
  a_1 &= 1 \\
  t_1 &= a_1 + b_0 \\
  a_2 &= 2 \\
  t_2 &= a_2 + b_0 \\
  a_3 &= \phi(a_1, a_2) \\
  t_3 &= a_3 + b_0
\end{align*}
\]

variable \(a_3\) isn't equivalent to either \(a_1\) or \(a_2\).
But, we can still remove a redundant computation of $a+b$ by moving the computation of $t_3$ to each of its predecessors:

\[
\begin{align*}
    a_1 &= 1 \\
    t_1 &= a_1 + b_0 \\
    e_1 &= a_1 + b_0 \\
    a_2 &= 2 \\
    t_2 &= a_2 + b_0 \\
    e_2 &= a_2 + b_0 \\
    e_3 &= \phi(e_1, e_2) \\
    t_3 &= e_3
\end{align*}
\]

Now a redundant computation of $a+b$ is evident in each predecessor block. Note too that this has a nice register targeting effect—$e_1$, $e_2$, and $e_3$ can be readily mapped to the same live range.
The notion of moving expression computations above phi functions also meshes nicely with notion of partial redundancy elimination. Given

\[
\begin{align*}
  a_1 &= 1 \\
  t_1 &= a_1 + b_0 \\
  a_2 &= 2 \\
  a_3 &= \phi(a_1, a_2) \\
  t_3 &= a_3 + b_0
\end{align*}
\]

moving \( a+b \) above the phi produces

\[
\begin{align*}
  a_1 &= 1 \\
  t_1 &= a_1 + b_0 \\
  a_2 &= 2 \\
  t_2 &= a_2 + b_0 \\
  t_3 &= \phi(t_1, t_2)
\end{align*}
\]

Now \( a+b \) is computed only once on each path, an improvement.
Project #4 Due Date Reset

- Your project #4 report is now due at 9 a.m. on Monday, December 17.

Reading Assignment

- Read "Global Optimization by Suppression of Partial Redundancies," Morel and Renvoise. (Linked from the class Web page.)
- Read “Profile Guided Code Positioning,” Pettis and Hansen. (Linked from the class Web page.)
Partial Redundancy Analysis

Partial Redundancy Analysis is a boolean-valued data flow analysis that generalizes available expression analysis.

Ordinary available expression analysis tells us if an expression must already have been evaluated (and not killed) along all execution paths.

Partial redundancy analysis, originally developed by Morel & Renvoise, determines if an expression has been computed along some paths. Moreover, it tells us where to add new computations of the expression to change a partial redundancy into a full redundancy.
This technique never adds computations to paths where the computation isn’t needed. It strives to avoid having any redundant computation on any path.

In fact, this approach includes movement of a loop invariant expression into a preheader. This loop invariant code movement is just a special case of partial redundancy elimination.
Basic Definition & Notation

For a Basic Block $i$ and a particular expression, $e$:

$\text{Transp}_i$ is true if and only if $e$’s operands aren’t assigned to in $i$.

$\text{Transp}_i \equiv \neg \text{Kill}_i$

$\text{Comp}_i$ is true if and only if $e$ is computed in block $i$ and is not killed in the block after computation.

$\text{Comp}_i \equiv \text{Gen}_i$
AntLoc$_i$ (Anticipated Locally in i) is true if and only if e is computed in i and there are no assignments to e’s operands prior to e’s computation. If AntLoc$_i$ is true, computation of e in block i will be redundant if e is available on entrance to i.
We’ll need some standard data flow analyses we’ve seen before:

\[ \text{AvIn}_i = \text{Available In for block } i \]

\[ = 0 \text{ (false) for } b_0 \]

\[ = \text{ AND } \text{AvOut}_p \]

\[ p \in \text{Pred}(i) \]

\[ \text{AvOut}_i = \text{Comp}_i \text{ OR } \]

\[ (\text{AvIn}_i \text{ AND Transp}_i) \]

\[ \equiv \text{ Gen}_i \text{ OR } \]

\[ (\text{AvIn}_i \text{ AND } \neg \text{Kill}_i) \]
We anticipate an expression if it is very busy:

\[ \text{AntOut}_i = \text{VeryBusyOut}_i \]

= 0 (false) if \( i \) is an exit block

\[ \text{AntOut}_i = \text{VeryBusyOut}_i \]

= \( \text{AND} \ \text{AntIn}_s \)
\[ s \in \text{Succ}(i) \]

\[ \text{AntIn}_i = \text{VeryBusyIn}_i \]

= \( \text{AntLoc}_i \ \text{OR} \)
\[ (\text{Transp}_i \ \text{AND} \ \text{AntOut}_i) \]
Partial Availability

Partial availability is similar to available expression analysis except that an expression must be computed (and not killed) along some (not necessarily all) paths:

\[ \text{PavIn}_i = 0 \text{ (false) for } b_0 \]

\[ = \text{OR PavOut}_p \quad p \in \text{Pred}(i) \]

\[ \text{PavOut}_i = \text{Comp}_i \text{ OR (PavIn}_i \text{ AND Transp}_i) \]
Where are Computations Added?

The key to partial redundancy elimination is deciding where to add computations of an expression to change partial redundancies into full redundancies (which may then be optimized away).
We’ll start with an “enabling term.”
\[\text{Const}_i = \text{AntLn}_i \ \text{AND} \ \ [\text{PavLn}_i \ \text{OR} \ (\text{Transp}_i \ \text{AND} \ \neg \ \text{AntLoc}_i)]\]

This term say that we require the expression to be:

(1) Anticipated at the start of block \( i \) (somebody wants the expression) and

(2a) The expression must be partially available (to perhaps transform into full availability)

or

(2b) The block neither kills nor computes the expression.
Next, we compute $\text{PP}_\text{In}_i$ and $\text{PP}_\text{Out}_i$. 

$\text{PP}$ means “possible placement” of a computation at the start ($\text{PP}_\text{In}_i$) or end ($\text{PP}_\text{Out}_i$) of a block.

These values determine whether a computation of the expression would be “useful” at the start or end of a basic block.

$\text{PP}_\text{Out}_i$

$= 0$ (false) for all exit blocks

$= \text{AND} \quad \text{PP}_\text{In}_s$

$s \in \text{Succ}(i)$

We try to move computations “up” (nearer the start block).

It makes sense to compute an expression at the end of a block if it makes sense to compute at the start of all the block’s successors.
\[ PPIn_i = 0 \text{ (false) for } b_0. \]

\[ = \text{Const}_i \]

\[ \text{AND (AntLoc}_i \text{ OR (Transp}_i \text{ AND PPOut}_i)) \]

\[ \text{AND (PPOut}_p \text{ OR AvOut}_p ) \]

\[ p \in \text{Pred}(i) \]

To determine if PPIn\(_i\) is true, we first check the enabling term. It makes sense to consider a computation of the expression at the start of block \( i \) if the expression is anticipated (wanted) and partially available or if the expression is anticipated (wanted) and it is neither computed nor killed in the block.

We then check that the expression is anticipated locally or that it is unchanged within the block and possibly positioned at the end of the block.
Finally, we check that all the block’s predecessors either have the expression available at their ends or are willing to position a computation at their end.

Note also, the bi-directional nature of this equation.
Inserting New Computations

After $\text{PPIn}_i$ and $\text{PPOut}_i$ are computed, we decide where computations will be inserted:

$$\\text{Insert}_i = \text{PPOut}_i \land (\neg \text{AvOut}_i) \land (\neg \text{PPIn}_i \lor \neg \text{Transp}_i)$$

This rule states that we really will compute the expression at the end of block $i$ if this is a possible placement point and the expression is not already computed and available and moving the computation still earlier doesn’t work because the start of the block isn’t a possible placement point or because the block kills the expression.
Removing Existing Computations

We’ve added computations of the expression to change partial redundancies into full redundancies. Once this is done, expressions that are fully redundant can be removed.

But where?

Remove$_i$ = AntLoc$_i$ and PPIIn$_i$

This rule states that we remove computation of the expression in blocks where it is computed locally and might be moved to the block’s beginning.
Partial Redundancy Subsumes Available Expression Analysis

Using partial redundancy analysis, we can find (and remove) ordinary fully redundant available expressions.

Consider a block, b, in which:

(1) The expression is computed (anticipated) locally

and

(2) The expression is available on entrance

Point (1) tells us that \( \text{AntLoc}_b \) is true
Moreover, recall that
\[ \text{PPIn}_b = \text{Const}_b \ \text{AND} \ (\text{AntLoc}_b \ \text{OR} \ ... \ ) \]
\[ \text{AND} \ (\text{AvOut}_p \ \text{OR} \ ... \ ) \]
\[ p \in \text{Pred}(i) \]

\[ \text{Const}_b = \text{AntIn}_b \ \text{AND} \ [\text{PavIn}_b \ \text{OR} \ ... \] \]

We know \( \text{AntLoc}_b \) is true \( \implies \text{AntIn}_b = \) true.

Moreover, \( \text{AvIn}_b = \) true \( \implies \text{PavIn}_b = \) true.

Thus \( \text{Const}_b = \) true.

If \( \text{AvIn}_b \) is true, \( \text{AvOut}_p \) is true for all \( p \in \text{Pred}(b) \).

Thus \( \text{PPIn}_b \ \text{AND} \ \text{AntLoc}_b = \) true = \( \text{Remove}_b \)
Are any computations added earlier (to any of b’s ancestors)?

No:

\[ \text{Insert}_i = \text{PPOut}_i \land (\neg \text{AvOut}_i) \land (\neg \text{PPl}_i \lor \neg \text{Transp}_i) \]

But for any ancestor, i, between the computation of the expression and b, \( \text{AvOut}_i \) is true, so \( \text{Insert}_i \) must be false.
Examples of Partial Redundancy Elimination

At block 3, \( x+3 \) is partially, but not fully, redundant.

\[
PPIn_3 = \text{Const}_3 \land (\text{AntLoc}_3 \lor \ldots ) \land (\text{PPOut}_p \lor \text{AvOut}_p) \quad p \in \text{Pred}(3)
\]

\[
\text{Const}_3 = \text{AntIn}_3 \land (\text{PavIn}_3 \lor \ldots )
\]

Now \( \text{AntIn}_3 = \text{true} \) and \( \text{PavIn}_3 = \text{true} \).

\[
\text{Const}_3 = \text{true} \land \text{true} = \text{true}
\]
PPout₁ = PPIn₃

Default initialization of PPIn and PPOut terms is true, since we AND terms together.

AntLoc₃ = true.

PPIn₃  = true AND true

AND (PPOutₚ OR AvOutₚ)  =  p ∈ Pred(3)

PPOut₁ AND AvOut₂= true AND true
= PPIn₃ = PPOut₁.

Insert₁ = PPOut₁ AND (¬ AvOut₁)

AND (¬ PPIn₁ OR ¬ Transp₁) =

PPOut₁ AND (¬ AvOut₁)
AND (¬ Transp₁) = true,

so x+3 is inserted at the end of block 3.
Remove_3 = AntLoc_3 and PPIn_3 = true AND true = true, so x+3 is removed from block 3.

Is x+3 inserted at the end of block 2? (It shouldn’t be).

Insert_2 = PPOut_2 AND (¬ AvOut_2) AND (¬ PPIn_2 OR ¬ Transp_2) = PPOut_2 AND false AND (¬ PPIn_2 OR ¬ Transp_2) = false.

We now have

![Diagram showing blocks with x=1, x=2, and x=3]
Computations May Move "Up" Several Blocks

Again, at block 4, \( x+3 \) is partially, but not fully, redundant.

\[ PPIn_4 = Const_4 \land (AntLoc_4 \lor \ldots) \]

\[ \land (PPOut_p \lor AvOut_p) \]

\( p \in \text{Pred}(4) \)
\[\text{Const}_4 = \text{AntIn}_4 \text{ AND } [\text{PavIn}_4 \text{ OR } ...]\]

Now \(\text{AntIn}_4 = \text{true}\) and \(\text{PavIn}_4 = \text{true}\).

\[\text{Const}_4 = \text{true AND true = true}\]

\[\text{PPout}_3 = \text{PPIn}_4.\]

\[\text{AntLoc}_4 = \text{true}.\]

\[\text{PPIn}_4 = \text{true } \text{ AND true}\]

\[\begin{align*}
&\text{AND} \\
&\ (\text{PPOut}_p \text{ OR AvOut}_p) = \\
&\ p \in \text{Pred}(4)
\end{align*}\]

\[\text{PPOut}_3 = \text{true}.\]

\[\text{PPIn}_3 = \text{Const}_3 \text{ AND } \]

\[\begin{align*}
&(\text{Transp}_3 \text{ AND PPOut}_3) \text{ OR } ... ) \\
&\text{AND} \\
&\ (\text{PPOut}_p \text{ OR AvOut}_p) = \\
&\ p \in \text{Pred}(3)
\end{align*}\]

\[\text{Const}_3 = \text{AntIn}_3 \text{ AND } [\text{PavIn}_3 \text{ OR } ...]\]

\[\text{AntIn}_3 = \text{true AND PavIn}_3 = \text{true}.\]
\[ \text{Const}_3 = \text{true AND true} = \text{true} \]
\[ \text{PPOut}_1 = \text{PPIn}_3 \]
\[ \text{Transp}_3 = \text{true.} \]
\[ \text{PPIn}_3 = \text{true AND (true AND true)} \]
\[ \quad \quad \quad \quad \text{AND} \quad (\text{PPOut}_p \text{ OR AvOut}_p) = \]
\[ \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \text{p} \in \text{Pred}(3) \]
\[ \text{PPOut}_1 \text{ AND AvOut}_2 = \text{true AND true} \]
\[ = \text{PPIn}_3 = \text{PPOut}_1. \]
Where Do We Insert Computations?

\[
\text{Insert}_3 = \text{PPOut}_3 \text{ AND } (\neg \text{AvOut}_3) \\
\text{AND } (\neg \text{PPI}\text{n}_3 \text{ OR } \neg \text{Transp}_3) = \\
\text{true AND (true) AND} \\
(\text{false OR false}) = \text{false}
\]

so \(x+3\) is \text{not} \text{ inserted at the end of block } 3.

\[
\text{Insert}_2 = \text{PPOut}_2 \text{ AND } (\neg \text{AvOut}_2) \\
\text{AND } (\neg \text{PPI}\text{n}_2 \text{ OR } \neg \text{Transp}_2) = \\
\text{PPOut}_2 \text{ AND (false)} \\
\text{AND (false OR false)}=\text{false},
\]

so \(x+3\) is \text{not} \text{ inserted at the end of block } 2.
Insert_1 = \text{PPOut}_1 \text{ AND } (\neg \text{AvOut}_1) \\
\text{AND } (\neg \text{PPIn}_1 \text{ OR } \neg \text{Transp}_1) = \\
\text{true AND (true) AND} \\
(\neg \text{PPIn}_1 \text{ OR true}) = \text{true} \\
\text{so } x+3 \text{ is inserted at the end of block 3.} \\
\text{Remove}_4 = \text{AntLoc}_4 \text{ and PPIn}_4 \\
= \text{true AND true = true, so } x+3 \text{ is removed from block 4.} \\
\text{We finally have}
Code Movement is Never Speculative

Partial redundancy analysis has the attractive property that it never adds a computation to an execution path that doesn’t use the computation. That is, we never speculatively add computations.

How do we know this is so? Assume we are about to insert a computation of an expression at the end of block b, but there is a path from b that doesn’t later compute and use the expression.

Say the path goes from b to c (a successor of b), and then eventually to an end node.
Looking at the rules for insertion of an expression:

\[
\text{Insert}_b = \text{PPOut}_b \land \ldots \\
\text{PPOut}_b = \text{PPInc}_c \land \ldots \\
\text{PPInc}_c = \text{Const}_c \land \ldots \\
\text{Const}_c = \text{AntInc}_c \land \ldots 
\]

But if the expression isn’t computed and used on the path through \(c\), then \(\text{AntInc}_c = \text{False}\), forcing \(\text{Insert}_b = \text{false}\), a contradiction.
Can Computations Always be Moved Up?

Sometimes an attempt to move a computation earlier in the CFG can be blocked. Consider

We’d like to move \( a + b \) into block 2, but this may be impossible if \( a + b \) isn’t anticipated on all paths out of block 2.

The solution to this difficulty is no notice that we really want \( a + b \) computed on the edge from 2 to 3.
If we add an artificial block between blocks 2 and 3, movement of \(a+b\) out of block 3 is no longer blocked:
Loop Invariant Code Motion

Partial redundancy elimination subsumes loop invariant code motion. Why?
The iteration of the loop makes the invariant expression partially redundant on a path from the expression to itself.
If we’re guaranteed the loop will iterate at least once (do-while or repeat-until loops), then evaluation of the expression can be anticipated in the loop’s preheader.
Consider

\[ a = \text{val} \]
\[ \text{do} \]
\[ \ldots \]
\[ a + b \]
\[ \ldots \]
\[ \text{while (\ldots)} \]
\[ PPI_{n_B} = Const_B \land (\text{AntLoc}_B \lor \ldots) \land (PPO_{n_p} \land \text{AvOut}_C) \]
\[ Const_B = \text{AntIn}_B \land [\text{PavIn}_B \lor \ldots] \]
\[ \text{AntIn}_B = \text{true, PavIn}_B = \text{true} \implies Const_B = \text{true} \]

\[ PPO_{n_p} = PPI_{n_B}, \text{AntLoc}_B = \text{true, } \text{AvOut}_C = \text{true} \implies PPI_{n_B} = \text{true.} \]

\[ \text{Insert}_{n_p} = PPO_{n_p} \land (\neg \text{AvOut}_{n_p}) \land (\neg \text{PPI}_{n_p} \lor \neg \text{Transp}_{n_p}) = \]
\[ \text{true and (true) and } (\neg \text{PPI}_{n_p} \lor \text{true}) = \text{true, so we may insert } a+b \text{ at the end of the preheader.} \]

\[ \text{Remove}_{n_B} = \text{AntLoc}_B \text{ and } PPI_{n_B} = \text{true and true, so we may remove } a+b \text{ from the loop body.} \]
What About While & For Loops?

The problem here is that the loop may iterate zero times, so the loop invariant isn’t really very busy (anticipated) in the preheader.

We can, however, change a while (or for) into a do while:

```c
while (expr){ if (expr)
    body ≡ do {body} ≈
} while (expr)
```

goto L:
    do {body}
L:
while (expr)

After we know the loop will iterate once, we can evaluate the loop invariant.

**Code Placement in Partial Redundancy Elimination**

While partial redundancy elimination correctly places code to avoid unnecessary reevaluation of expressions along execution paths, its choice of code placement can sometimes be disappointing. It always moves an expression back as far as possible, as long as computations aren’t added to unwanted execution paths. This may unnecessarily lengthen live ranges, making register allocation more difficult.
For example, in

\[
\begin{align*}
  a &= \text{val} \\
  \therefore \quad a+b
\end{align*}
\]

where will we insert \( a+b \)?

\[
\text{Insert}_p = \text{PPOut}_p \land (\neg \text{AvOut}_p) \land (\neg \text{PPIp}_p \lor \neg \text{Transp}_p)
\]

The last term will be true at the top block, but not elsewhere.
In “Lazy Code Motion” (PLDI 1992), Knoop, Ruething and Steffan show how to eliminate partial redundancies while minimizing register pressure. Their technique seeks to evaluate an expression as “late as possible” while still maintaining computational optimality (no redundant or unnecessary evaluations on any execution paths).

Their technique places loop invariants in the loop preheader rather than in an earlier predecessor block as Morel & Renvoise do.
Partial Dead Code Elimination

Partial Redundancy Elimination aims to never reevaluate an expression on any path, and never to add an expression on any path where it isn’t needed.

These ideas suggest an interesting related optimization—eliminating expressions that are partially dead.

Consider

\[ y = a + b \]

\[ y = 0 \]

print(y)
On the left execution path, \( a+b \) is dead, and hence useless. We’d prefer to compute \( a+b \) only on paths where it is used, obtaining

\[
\begin{align*}
\text{y=0} & \quad \text{y=a+b} \\
& \quad \text{print(y)}
\end{align*}
\]

This optimization is investigated in “Partial Dead Code Elimination” (PLDI 1994), Knoop, Ruething and Steffan. This optimization “sinks” computations onto paths where they are needed.
Procedure & Code Placement

We have seen many optimizations that aim to reduce the number of instructions executed by a program. Another important class of optimizations derives from the fact that programs often must be paged in virtual memory and almost always are far bigger than the I-cache.

Hence how procedures and basic blocks are placed in memory is important. Page faults and I-cache misses can be very costly.
In “Profile Guided Code Positioning,” Pettis and Hansen explore three kinds of code placement optimizations:

1. Procedure Positioning.
   Try to keep procedures that often call each other close together.

2. Basic Block Positioning.
   Try to place the most frequently executed series of basic blocks “in sequence.”

   Place infrequently executed “fluff” in a different memory area than heavily executed code.
Procedure Placement

Procedures (and classes in Java) are normally separately compiled. They are then placed in memory by a linker or loader in an arbitrary order. This arbitrary ordering can be problematic:

If A calls B frequently, and A and B happen to be placed far apart in memory, the calls will cross page boundaries and perhaps cause L-cache conflicts (if code in A and B happen to map to common cache locations).

However, if A and B are placed close together in memory, they may both fit on the same page and fit into the L-cache without conflicts.
Pettis & Hansen suggest a “closest is best” procedure placement policy. That is, they recommend that we place procedures that often call each other as close together as possible.

How?
First, we must obtain dynamic call frequencies using a profiling tool like gprof or qpt.
Given call frequencies, we create a call graph, with edges annotated with call frequencies:

![Call Graph Diagram]

- A → C: 4
- A → D: 10
- C → F: 8
- C → D: 3
- D → E: 2
- F → E: 1
Group Procedures by Call Frequency

We find the pair of procedures that call each other most often, and group them for contiguous positioning.

The notation \([A,D]\) means A and D will be adjacent (either in order A-D or D-A).

The two procedures chosen are combined in the call graph, which is simplified (much like move-related nodes in an interference graph):

```
  C    7   [A,D]
   8      2
  F   1
   E
```
Now C and F are grouped, without their relative order set (as yet):

Next [A,D] and [C,F] are to be joined, but in what exact order?

Four orderings are possible:

- A- D- C- F $\equiv$ F- C- D- A
- A- D- F- C $\equiv$ C- F- D- A
- D- A- C- F $\equiv$ F- C- A- D
- D- A- F- C $\equiv$ C- F- A- D

Are these four orderings equivalent?
No—Look at the original call graph. At the boundary between [A,D] and [C,F], which of the following is best:

- D- C (3 calls),
- D- F (0 calls)
- A- C (4 calls)
- A- F (0 calls)

A- C has the highest call frequency, so we choose D- A- C- F.

Finally, we have:

We place E near D (call frequency 2) rather than near F (call frequency 1).

Our final ordering is E- D- A- C- F.
Basic Block Placement

We often see conditionals of the form

```c
default if (error-test) {
    Handle error case

    Rest of Program
```

Since error tests rarely succeed (we hope!), the error handling code “pollutes” the I-cache.

In general, we’d like to order basic blocks not in their order of appearance in the source program, but rather in order of their execution along frequently executed paths.

Placing frequently executed basic blocks together in memory fills the I-cache nicely, leads to a smaller working set and makes branch prediction easier.
Pettis & Hansen suggest that we profile execution to determine the frequency of inter-block transitions. We then will group blocks together that execute in sequence most often. At the start, all basic blocks are grouped into singleton chains of one block each.

Then, in decreasing order of transition frequency, we visit arcs in the CFG. If the blocks in the source and target can be linked into a longer chain then do so, else skip to the next transition.

When we are done, we have linked together blocks in paths in the CFG that are most frequently executed.
Linked basic blocks are allocated together in memory, in the sequence listed in the chain.
Example

\[
\begin{align*}
A & \rightarrow B & 1000 \\
B & \rightarrow C & 7000 \\
C & \rightarrow D & 6500 \\
C & \rightarrow E & 6500 \\
D & \rightarrow F & 4000 \\
D & \rightarrow G & 500 \\
E & \rightarrow H & 2500 \\
F & \rightarrow H & 4000 \\
G & \rightarrow I & 500 \\
G & \rightarrow I & 500 \\
E & \rightarrow I & 900 \\
D & \rightarrow I & 2500 \\
B & \rightarrow I & 6500 \\
A & \rightarrow I & 2500 \\
\end{align*}
\]
Initially, each bock is in its own chain.

<table>
<thead>
<tr>
<th>Frequency</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>2500</td>
<td>H is already placed</td>
</tr>
<tr>
<td>1000</td>
<td>A can’t be placed before B, leave it alone</td>
</tr>
<tr>
<td>900</td>
<td>I can’t be placed after B, leave it alone</td>
</tr>
<tr>
<td>500</td>
<td>G can’t be placed after C, leave it alone</td>
</tr>
<tr>
<td>500</td>
<td>Form G- I</td>
</tr>
</tbody>
</table>
We will place in memory the following chains of basic blocks:

H- B- C- D- F, E, A, G- I

On some computers, the direction of a conditional branch predicts whether the branch is expected to be taken or not (e.g., the HP PA-RISC). On such machines, a backwards branch (forming a loop) is assumed taken; a forward branch is assumed not taken.

If the target architecture makes such assumptions regarding conditional branches, we place chains to (where possible) correctly predict the branch outcome.

Thus E and G- I are placed after H- B- C- D- F since D→E and C→G normally aren’t taken.
On the SPARC (V 9) you can set a bit in each conditional branch indicating expected taken/not taken status.
On many machines internal branch prediction hardware can over-rule poorly made (or absent) static predictions.
Procedure Splitting

When we profile the basic blocks within a procedure, we’ll see some that are frequently executed, and others that are executed rarely or never.

If we allocate all the blocks of a procedure contiguously, we’ll intermix frequently executed blocks with infrequently executed ones.

An alternative is “fluff removal.” We can split a procedure’s body into two sets of basic blocks: these executed frequently and those executed infrequently (the dividing line is, of course, somewhat arbitrary).
Now when procedure bodies are placed in memory, frequently executed basic blocks will be placed near each other, and infrequently executed blocks will be placed elsewhere (though infrequently executed blocks are still placed near each other). In this way be expect to make better use of page frames and I-cache space, filling them with mostly active basic blocks.
