

We anticipate an expression if it is very busy: AntOut_i = VeryBusyOut_i = 0 (false) if i is an exit block = AND AntIn_s $s \in Succ(i)$ AntIn_i = VeryBusyIn_i

 AntLoc_i OR (Transp_i AND AntOut_i)

Partial Availability

Partial availability is similar to available expression analysis except that an expression must be computed (and not killed) along *some* (not necessarily *all*) paths:

Pavln_i

= 0 (false) for b_0

 $= \begin{array}{c} OR \quad \mathsf{PavOut}_p \\ p \in \mathsf{Pred}(i) \end{array}$

```
PavOut<sub>i</sub> = Comp<sub>i</sub> OR
(PavIn<sub>i</sub> AND Transp<sub>i</sub>)
```

Where are Computations Added?

The key to partial redundancy elimination is deciding where to add computations of an expression to change partial redundancies into full redundancies (which may then be optimized away). We'll start with an "enabling term."

Const_i = AntIn_i AND

[PavIn_i OR (Transp_i AND – AntLoc_i)]

This term say that we require the expression to be:

(1) Anticipated at the start of block i (somebody wants the expression) and

(2a) The expression must be partially available (to perhaps transform into full availability)

or

(2b) The block neither kills nor computes the expression.

Next, we compute $PPIn_i$ and $PPOut_i$. PP means "possible placement" of a computation at the start ($PPIn_i$) or end ($PPOut_i$) of a block.

These values determine whether a computation of the expression would be "useful" at the start or end of a basic block.

PPOut_i

= 0 (false) for all exit blocks

$$= AND PPIn_{S}$$

s \in Succ(i)

We try to move computations "up" (nearer the start block).

It makes sense to compute an expression at the end of a block if it makes sense to compute at the start of all the block's successors. $PPIn_i = 0$ (false) for b_0 .

= Const_i

AND (AntLoc_i OR (Transp_i AND PPOut_i))

```
AND (PPOut<sub>p</sub> OR AvOut<sub>p</sub>)
p \in Pred(i)
```

To determine if PPIn_i is true, we first check the enabling term. It makes sense to consider a computation of the expression at the start of block i if the expression is anticipated (wanted) and partially available or if the expression is anticipated (wanted) and it is neither computed nor killed in the block.

We then check that the expression is anticipated locally or that it is unchanged within the block and possibly positioned at the end of the block. Finally, we check that all the block's predecessors either have the expression available at their ends or are willing to position a computation at their end.

Note also, the bi-directional nature of this equation.

Inserting New Computations

After PPIn_i and PPOut_i are computed, we decide where computations will be inserted:

Insert_i = PPOut_i AND (¬ AvOut_i) AND (¬ PPIn_i OR ¬ Transp_i)

This rule states that we really will compute the expression at the end of block i if this is a possible placement point and the expression is not already computed and available and moving the computation still earlier doesn't work because the start of the block isn't a possible placement point or because the block kills the expression.

Removing Existing Computations

We've added computations of the expression to change partial redundancies into full redundancies. Once this is done, expressions that are fully redundant can be removed. But where?

Remove_i = AntLoc_i and PPIn_i

This rule states that we remove computation of the expression in blocks where it is computed locally and might be moved to the block's beginning.

Partial Redundancy Subsumes Available Expression Analysis

Using partial redundancy analysis, we can find (and remove) ordinary fully redundant available expressions.

Consider a block, b, in which:

(1) The expression is computed (anticipated) locally

and

(2) The expression is available on entrance

Point (1) tells us that AntLoc_b is true

```
Moreover, recall that
```

```
PPIn_b = Const_b AND
(AntLoc<sub>b</sub> OR ... )
```

```
AND (AvOut p \text{ OR } \dots)
p \in Pred(i)
```

 $Const_b = AntIn_b AND [PavIn_b OR ...]$

We know AntLoc_b is true \Rightarrow AntIn_b = true.

Moreover, $AvIn_b = true \implies PavIn_b = true$.

Thus $Const_b = true$.

If $AvIn_b$ is true, $AvOut_p$ is true for all $p \in Pred(b)$.

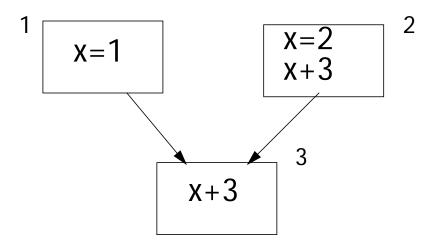

```
Thus PPIn<sub>b</sub> AND AntLoc<sub>b</sub> = true = Remove<sub>b</sub>
```

Are any computations added earlier (to any of b's ancestors)? No:

Insert_i = PPOut_i AND (¬ AvOut_i) AND (¬ PPIn_i OR ¬ Transp_i)

But for any ancestor, i, between the computation of the expression and b, AvOut_i is true, so Insert_i must be false.

Examples of Partial Redundancy Elimination

At block 3, x+3 is partially, but not fully, redundant.

 $PPIn_3 = Const_3 AND$ (AntLoc₃ OR ...)

AND (PPOut_p OR AvOut_p) $p \in Pred(3)$

Const₃ = AntIn₃ AND [PavIn₃ OR ...] Now AntIn₃ = true and PavIn₃ = true. Const₃ = true AND true = true

```
PPout_1 = PPIn_3
```

Default initialization of PPIn and PPOut terms is true, since we AND terms together.

 $AntLoc_3 = true.$

 $PPIn_3 = true AND true$

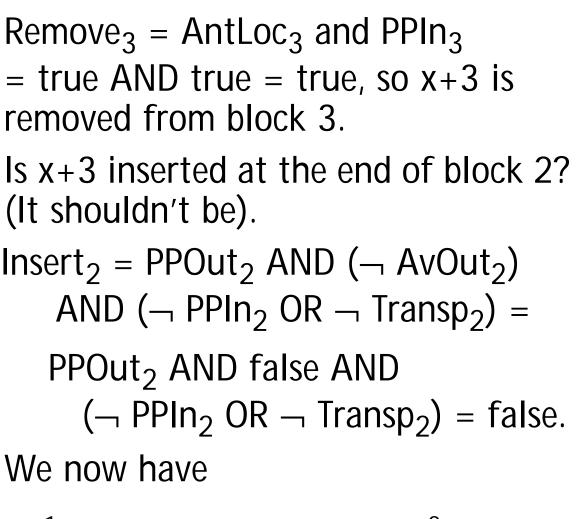

AND (PPOut_p OR AvOut_p) = $p \in Pred(3)$

 $PPOut_1 AND AvOut_2 = true AND true = PPIn_3 = PPOut_1.$

Insert₁ = PPOut₁ AND (\neg AvOut₁) AND (\neg PPIn₁ OR \neg Transp₁) =

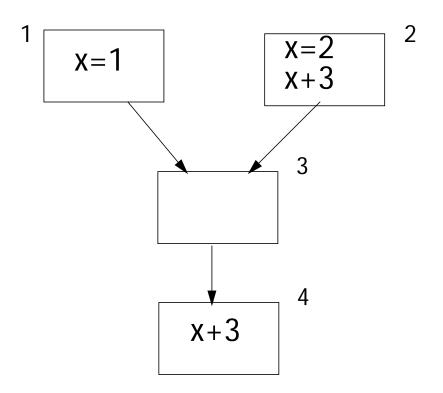

PPOut₁ AND (\neg AvOut₁) AND (\neg Transp₁) = true,

so x+3 is inserted at the end of block 3.

Computations May Move Up Several Blocks

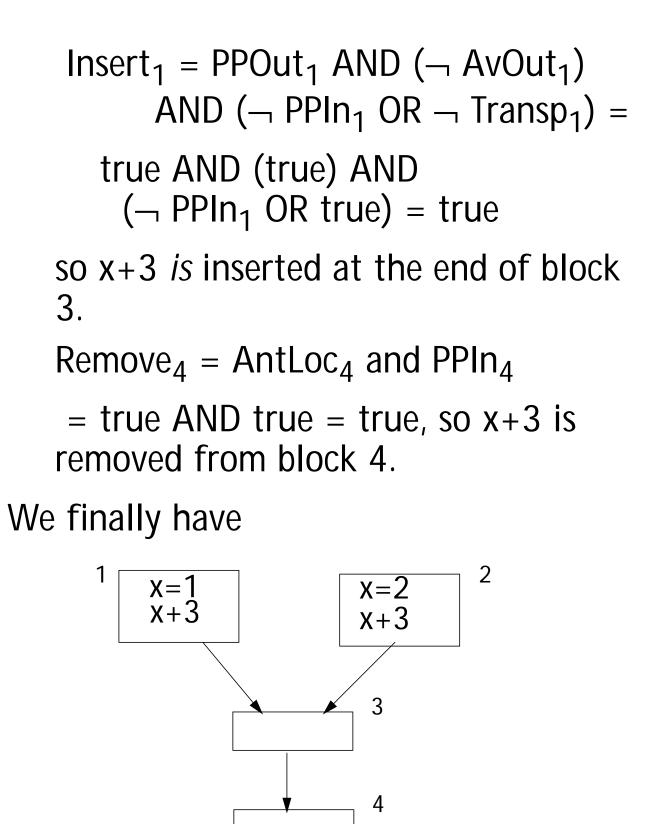

Again, at block 4, x+3 is partially, but not fully, redundant. PPIn₄ = Const₄ AND (AntLoc₄ OR ...) AND (PPOut_p OR AvOut_p) $p \in Pred(4)$

```
Const_4 = AntIn_4 AND [PavIn_4 OR ...]
Now AntIn<sub>\Delta</sub> = true and PavIn<sub>\Delta</sub> = true.
Const_4 = true AND true = true
PPout_3 = PPIn_4.
AntLoc<sub>4</sub> = true.
PPIn_4 = true AND true
  AND (PPOut<sub>p</sub> OR AvOut<sub>p</sub>) =
    p \in Pred(4)
PPOut_3 = true.
PPIn_3 = Const_3 AND
  ((Transp<sub>3</sub> AND PPOut<sub>3</sub>) OR ... )
  AND (PPOutp OR AvOutp)
    p \in Pred(3)
Const_3 = AntIn_3 AND [PavIn_3 OR ...]
Antln<sub>3</sub> = true and Pavln<sub>3</sub> = true.
```

Const₃ = true AND true = true PPOut₁ = PPIn₃ Transp₃ = true. PPIn₃ = true AND (true AND true) AND (PPOut_p OR AvOut_p) = $p \in Pred(3)$ PPOut₁ AND AvOut₂ = true AND true = PPIn₃ = PPOut₁.

Where Do We Insert Computations?

 $Insert_3 = PPOut_3 AND (\neg AvOut_3)$ AND (\neg PPIn₃ OR \neg Transp₃) = true AND (true) AND (false OR false) = false so x+3 is *not* inserted at the end of block 3. Insert₂ = PPOut₂ AND (\neg AvOut₂) AND $(\neg PPIn_2 OR \neg Transp_2) =$ PPOut₂ AND (false) AND (\neg PPIn₂ OR \neg Transp₂)=false, so x+3 is *not* inserted at the end of block 2.

Code Movement is Never Speculative

Partial redundancy analysis has the attractive property that it never adds a computation to an execution path that doesn't use the computation.

That is, we never *speculatively* add computations.

How do we know this is so?

Assume we are about to insert a computation of an expression at the end of block b, but there is a path from b that doesn't later compute and use the expression.

Say the path goes from b to c (a successor of b), and then eventually to an end node.

```
Looking at the rules for insertion of an expression:
```

```
Insert<sub>b</sub> = PPOut<sub>b</sub> AND ...
```

```
PPOut_b = PPIn_c AND ...
```

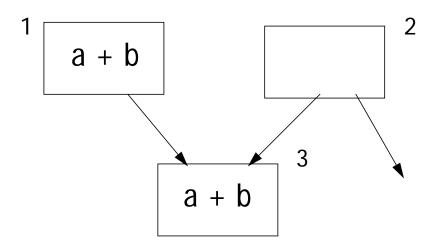

```
PPIn_c = Const_c AND \dots
```

 $Const_{c} = AntIn_{c} AND ...$

But if the expression isn't computed and used on the path through c, then $AntIn_c = False$, forcing $Insert_b = false$, a contradiction.

Can Computations Always be Moved Up?

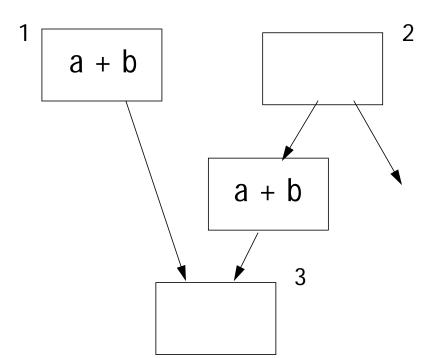

Sometimes an attempt to move a computation earlier in the CFG can be *blocked*. Consider

We'd like to move a+b into block 2, but this may be impossible if a+b isn't anticipated on all paths out of block 2.

The solution to this difficulty is no notice that we really want a+b computed on the *edge* from 2 to 3.

If we add an *artificial* block between blocks 2 and 3, movement of a+b out of block 3 is no longer blocked:

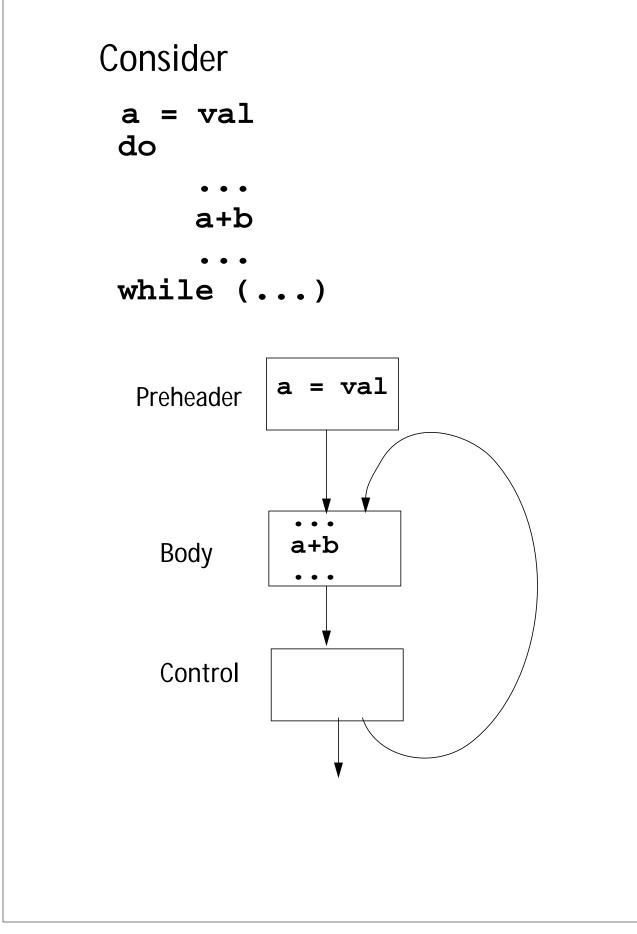

Loop Invariant Code Motion

Partial redundancy elimination subsumes loop invariant code motion. Why?

The iteration of the loop makes the invariant expression partially redundant on a path from the expression to itself.

If we're guaranteed the loop will iterate at least once (do-while or repeat-until loops), then evaluation of the expression can be anticipated in the loop's preheader.

 $PPIn_{B} = Const_{B} AND$ (AntLoc_B OR ...) AND (PPOut_p AND AvOut_C) $Const_{R} = AntIn_{R} AND [PavIn_{R} OR ...]$ AntIn_B = true, PavIn_B = true \Rightarrow $Const_{R} = true$ $PPout_{P} = PPIn_{B}$, $AntLoc_{B} = true$, AvOut_C = true \Rightarrow PPIn_B = true. Insert_P = PPOut_P AND (\neg AvOut_P) AND (\neg PPIn_P OR \neg Transp_P) = true AND (true) AND $(\neg PPIn_P OR true) = true,$ so we may insert a+b at the end of the preheader. $Remove_{R} = AntLoc_{R}$ and $PPIn_{R} =$ true AND true, so we may remove a+b from the loop body.

What About While & For Loops?

The problem here is that the loop may iterate zero times, so the loop invariant isn't really very busy (anticipated) in the preheader.

We can, however, change a while (or for) into a do while:

while (expr){ if (expr) body ≡ do {body} ≈ } while (expr)

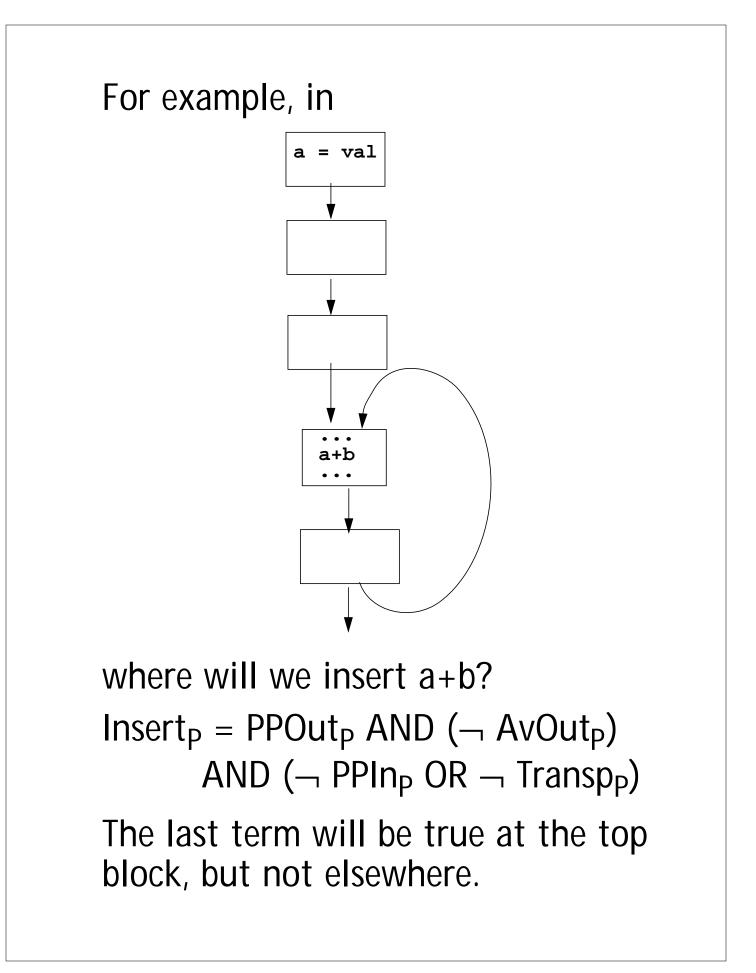

```
goto L:
do {body}
L:
while (expr)
```

After we know the loop will iterate once, we can evaluate the loop invariant.

Code Placement in Partial Redundancy Elimination

While partial redundancy elimination correctly places code to avoid unnecessary reevaluation of expressions along execution paths, its choice of code placement can sometimes be disappointing.

It always moves an expression back as far as possible, as long as computations aren't added to unwanted execution paths. This may unnecessarily lengthen live ranges, making register allocation more difficult.

In "Lazy Code Motion" (PLDI 1992), Knoop, Ruething and Steffan show how to eliminate partial redundancies while minimizing register pressure.

Their technique seeks to evaluate an expression as "late as possible" while still maintaining computational optimality (no redundant or unnecessary evaluations on *any* execution paths).

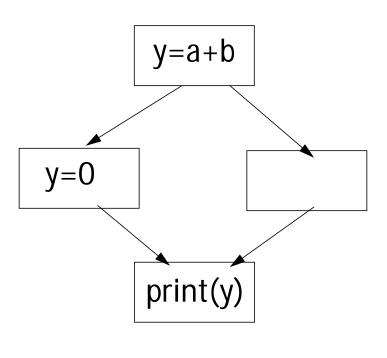

Their technique places loop invariants in the loop preheader rather than in an earlier predecessor block as Morel & Renvoise do.

Partial Dead Code Elimination

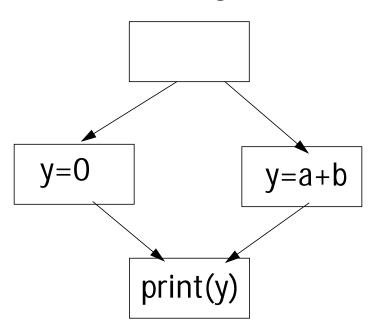

Partial Redundancy Elimination aims to never reevaluate an expression on any path, and never to add an expression on any path where it isn't needed.

These ideas suggest an interesting related optimization—eliminating expressions that are partially dead.

Consider

On the left execution path, a+b is dead, and hence useless. We'd prefer to compute a+b only on paths where it is used, obtaining

This optimization is investigated in "Partial Dead Code Elimination" (PLDI 1994), Knoop, Ruething and Steffan.

This optimization "sinks" computations onto paths where they are needed.
