4. The Abstraction: The Process

Operating System: Three Easy Pieces

How to provide the illusion of many CPUs?

CPU virtualizing

- The OS can promote the <u>illusion</u> that many virtual CPUs exist.
- Time sharing: Running one process, then stopping it and running another
 - The potential cost is performance.

A Process

A process is a running program.

- **D** Comprising of a process:
 - Memory (address space)
 - Instructions
 - Data section
 - Registers
 - Program counter
 - Stack pointer

D These APIs are available on any modern OS.

Create

• Create a new process to run a program

Destroy

- Halt a runaway process
- Wait
 - Wait for a process to stop running

Miscellaneous Control

• Some kind of method to suspend a process and then resume it

Status

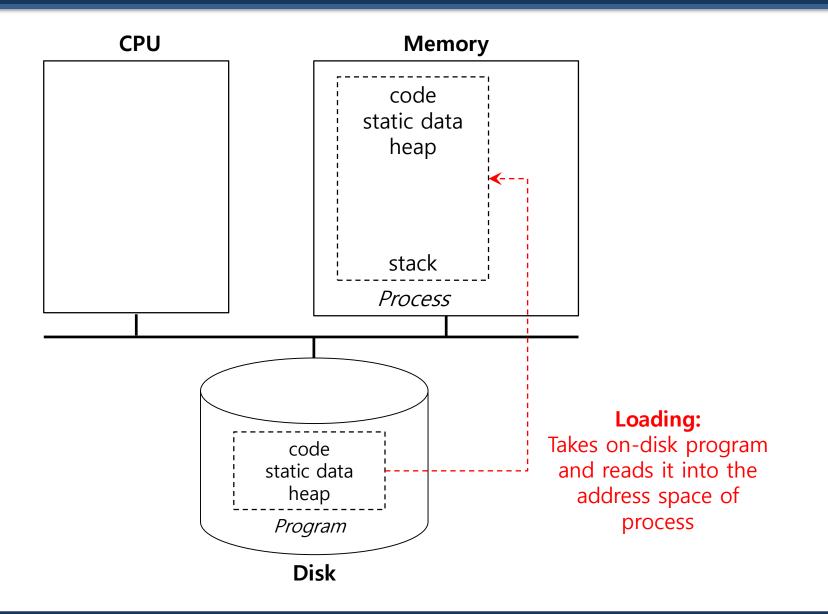

• Get some status info about a process

- 1. Load a program code into <u>memory</u>, into the address space of the process.
 - Programs initially reside on disk in *executable format*.
 - OS perform the loading process lazily.
 - Loading pieces of code or data only as they are needed during program execution.
- 2. The program's run-time **stack** is allocated.
 - Use the stack for *local variables, function parameters,* and *return address.*
 - Initialize the stack with arguments → argc and the argv array of main()
 function

Process Creation (Cont.)

- 3. The program's **heap** is created.
 - Used for explicitly requested dynamically allocated data.
 - Program request such space by calling malloc() and free it by calling free().
- 4. The OS do some other initialization tasks.
 - input/output (I/O) setup
 - Each process by default has three open file descriptors.
 - Standard input, output and error
- 5. Start the program running at the entry point, namely main().
 - The OS *transfers control* of the CPU to the newly-created process.

Loading: From Program To Process

Process States

■ A process can be one of three states.

Running

• A process is running on a processor.

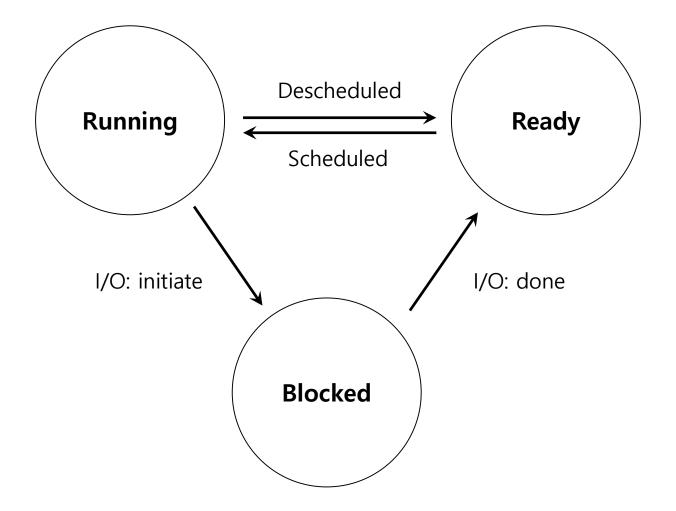

Ready

• A process is ready to run but for some reason the OS has chosen not to run it at this given moment.

Blocked

- A process has performed some kind of operation.
- When a process initiates an I/O request to a disk, it becomes blocked and thus some other process can use the processor.

Process State Transition

Data structures

- The OS has some key data structures that track various relevant pieces of information.
 - Process list
 - Ready processes
 - Blocked processes
 - Current running process
 - Register context
- PCB(Process Control Block)
 - A C-structure that contains information about each process.

```
// the registers xv6 will save and restore
// to stop and subsequently restart a process
struct context {
   int eip; // Index pointer register
   int esp; // Stack pointer register
   int ebx; // Called the base register
   int ecx; // Called the counter register
   int edx; // Called the data register
   int esi; // Source index register
   int edi; // Destination index register
   int ebp; // Stack base pointer register
};
// the different states a process can be in
enum proc state { UNUSED, EMBRYO, SLEEPING,
                 RUNNABLE, RUNNING, ZOMBIE };
```

```
// the information xv6 tracks about each process
// including its register context and state
struct proc {
   char *mem;
                             // Start of process memory
   uint sz;
                             // Size of process memory
   char *kstack;
                             // Bottom of kernel stack
                             // for this process
   enum proc state state; // Process state
   int pid;
                             // Process ID
                             // Parent process
   struct proc *parent;
   void *chan;
                             // If non-zero, sleeping on chan
                             // If non-zero, have been killed
   int killed;
   struct file *ofile[NOFILE]; // Open files
   struct inode *cwd; // Current directory
   struct context context; // Switch here to run process
   struct trapframe *tf; // Trap frame for the
                             // current interrupt
};
```
